We propose a way of fast switching the chirality in a magnetic nanodisk by applying a field pulse. To break the symmetry with respect to clockwise or counterclockwise chirality a mask is added by which an inhomogeneous field influences the vortex state of a nanodisk. Using numerical spin–lattice simulations we demonstrate that chirality can be controllably switched by a field pulse, whose intensity is above some critical value. A mathematical definition for the chirality of an arbitrary shaped particle is proposed.

In the last few years the nonlinear dynamics of magnetic nanostructures has been extensively studied in order to develop useful devices for storage and transmission of information. Magnetic nanodots with their vortex ground state show a considerable promise as candidates for high density magnetic storage and high speed magnetic random access memory [1]. The vortex state disks are characterized by the following conserved quantities, which can be associated with a bit of information: the polarity, the sense of the vortex core magnetization direction (up or down) and the chirality or handedness, the sense of magnetization rotation (clockwise or counterclockwise). Until recently the main efforts went into the control of vortex polarity and vortex motion inside the nanodots. The polarity switching under the action of an ac magnetic field was predicted theoretically [2] and was recently observed experimentally in Permalloy nanodisks by using short bursts of an ac magnetic field [3]. The polarity switching under the action of a dc electrical current was predicted theoretically [4] and observed experimentally quite recently [5]. The main features of the polarity switching mechanism were clarified in Refs. [3, 6, 7, 8, 9, 10], where it was shown that no matter whether the switching is induced by a magnetic field or by an electrical current it involves creation of a vortex-antivortex pair and subsequent annihilation of the new-born anti-vortex with the original vortex.

In standard experiments with in-plane field and circular nanodisks the vortex chirality is not under control because of the high symmetry of the system [11]. However, the chirality is known to be controlled by introducing an asymmetry in the particle shape, like flat edges of the disk [12, 13], rings with asymmetrical inner holes [14], and elliptical dots [15, 16]. Quite recently it was demonstrated [17] that the vortex chirality can be switched by injecting a current pulse with appropriate amplitude, polarity and duration. This was achieved in a multilayer structure with two different magnetic layers, each being in a vortex state.

The aim of the present Letter is to show that the vortex chirality can be controllably switched by applying a magnetic field pulse in a circular magnetic disk. We use the disk–shaped particle in a vortex state, see Fig. 1. A magnetic field is applied in the disk plane, which moves the vortex away from the disk center. If the homogeneous DC field exceeds the value $b_{an}$, the vortex is annihilated, and finally the vortex state switches to the monodomain state [18]. After that the field is switched off, and a vortex enters the system, however the chirality of the new-born vortex could be either clockwise or counterclockwise [11]. To control the chirality of nucleated vortex one needs to break the symmetry with respect to chirality. We propose to break it by inhomogeneous field, which can be simply realized, e.g. by using a mask, which shields a part of the disk from the field influence, see Fig. 1.

To realize this program let us consider the dynamics of classical lattice spins, described by the Landau–Lifshitz–Gilbert equations

$$\frac{dS_n}{d\tau} = -S_n \times \frac{\partial \mathcal{H}}{\partial S_n} - \alpha S_n \times \frac{dS_n}{d\tau},$$

(1)

where $S_n$ is a unit vector which determines the spin direction at the lattice point $n$, the lattice constant is cho-
In an external dc magnetic field $b$, which is stronger than some annihilation field $b_{\text{an}}$, but below the saturation field $b_{\text{sat}}$, the monodomain state appears. However, if the field $b$ is inhomogeneous, the monodomain state is nonuniform. By choosing the shape of the field, one can create this intermediate monodomain state with a certain nonzero chirality. After that, if we switch off the field, the vortex will be nucleated with a predefined chirality.

To study the vortex dynamics, we have performed numerical simulations of the discrete spin-lattice Eqs. (1). We consider the case of thin nanodots where the magnetization does not depend on the $z$-coordinate, the details of the method are described in Ref. [19]. We have integrated numerically the set of Eqs. (1) over a square lattice using the fourth-order Runge-Kutta scheme with time step $\Delta t = 0.01$. The lattice is bounded by a circle of diameter $2R$. In most of the simulations the system diameter $2R = 50$, the thickness $h = 10$, other parameters: $\ell = 1.33$, $\alpha = 0.01$. We applied an inhomogeneous field along the $x$ axis by the shape $b(x, y) = b\Theta(\xi - x)\Theta(\xi - y)$ with $\Theta(x)$ being the Heaviside step function. We choose $\xi/(2R) = 0.85$. Such a field can be realized by a mask which covers a part of the disk, see Fig. 2(a).

The temporal evolution of the chirality is presented in Fig. 2(a). Initially the chirality was $C = -1$ (counterclockwise), see Fig. 2(b). Under the action of the field pulse the vortex is pushed away in the direction of the north pole of the disk, which is accompanied by a decrease of the absolute value of the chirality, see Fig. 2(c). The next monodomain stage is presented in Fig. 2(d). The vortex is already annihilated, but the total chirality takes a nonzero (positive) value due to the mask influence. After that the field pulse is switched off, and the new vortex enters the disk from the south pole with a predefined (positive) chirality, see Fig. 2(e). This vortex quickly moves to the disk center, and finally the chirality is $C = +1$ (clockwise), see Fig. 2(f). The switching process takes place in a wide range of parameters of the field pulse, when the field intensity $b > b_{\text{an}}$, see Fig. 2.

Using typical parameters for permalloy disks [20], one can estimate the exchange length $\ell = 5.3\,\text{nm}$, which corresponds to a particle with $2R = 200\,\text{nm}$ and $h = 40\,\text{nm}$. The typical time unit $1/\omega_0 = 50\,\text{ps}$ and the field unit $4\pi M_S = 10\,\text{kOe}$. The typical switching field intensity is about $140\,\text{Oe}$ and the typical switching time is about $7\,\text{ns}$.

To summarize, we have studied the chirality switching...
under the action of a dc magnetic field. In contrast to previous studies on the chirality control, we showed that the switching can be managed in a pure disk nanoparticle: to break the symmetry the usage of the mask is proposed. Usually the chirality is considered as either clockwise or counterclockwise. By considering the chirality as a continuous quantity, we were able to control the switching process: the key point is an intermediate state with a nonzero chirality. We consider here only one possible realization of the chirality switching with a very simple mask. We expect that the usage of a mask will be prominent for different applications of nonlinear magnetization dynamics in nanoparticles.

The authors thank H. Stoll and M. Fähnle for stimulating discussions. D.S., Yu.G. thank the University of Bayreuth, where this work was performed, for kind hospitality, and acknowledge the support from DLR grant No. UKR 05/055. D.S. acknowledges the support from the Alexander von Humboldt—Foundation and the grant No. F25.2/098 from the Fundamental Researches State Fund of Ukraine.
