Nucleolar organiser regions (AgNORs) as predictors in transitional cell bladder cancer

P.K. Lipponen1, M.J. Eskelinen2 & S. Nordling3

Departments of 1Pathology and 2Surgery, University of Kuopio; and 3Department of Pathology, University of Helsinki, Finland.

Summary The predictive value of silver stained nucleolar organiser regions (AgNORs) was assessed in 229 patients with transitional cell bladder cancer followed up for over 10 years. The AgNORs were enumerated in pretreatment biopsy specimens. The AgNORs were related to clinical stage (T)(P = 0.0111), papillarity (P < 0.0001), WHO grade (P < 0.0001), DNA ploidy (P = 0.0010) and S-phase fraction (P < 0.0001). Tumours presenting with pelvic lymph node involvement (P = 0.0085) or metastasis (P = 0.0780) at the time of diagnosis had more AgNORs than tumours confined to the bladder wall. Progression in T-, N- and M-categories (P = 0.0010–0.0030) was related to AgNORs and consequently they predicted bladder cancer related survival (P = 0.0005). The diploid tumours could be regrouped according to survival by AgNORs (P = 0.0001). In papillary tumours AgNORs predicted progression (P = 0.0110) and survival (P = 0.0038). In Ta-T1 tumours AgNORs contributed to survival significantly (P = 0.0039). The AgNORs subdivided WHO grade III tumours according to their ability to progress during the follow-up time (P = 0.0711). In a multivariate analysis AgNORs predicted progression independently in Ta-T1 category (P = 0.0165). AgNORs predicted recurrence free period like SPF (P = 0.0010). In conclusion, AgNORs are inferior to classic prognostic factors or DNA flow cytometric variables in muscle invasive bladder cancers whereas they have independent predictive value in superficial cancers.

Subjective grading systems are unable to precisely predict cancer behaviour (Blomjous et al., 1989; Eskelinen et al., 1991a; Lipponen & Eskelinen, 1990a). To obtain more accurate pretreatment estimates of survival, quantitative methods (Blomjous et al., 1989; Eskelinen et al., 1991a; Lipponen & Eskelinen, 1990b, c) have been tested to define new clinically relevant variables in place for subjective grading (Ooms et al., 1983). Particularly, quantitative variables reflecting proliferative activity of cancer cells have had the highest predictive potential (Blomjous et al., 1989; Eskelinen et al., 1991b; Lipponen & Eskelinen, 1990b, c). AgNORs (Lipponen et al., 1990b, c; Lipponen et al., 1990b) are significant predictors in transitional cell bladder cancer including similar prognostic information (Lipponen et al., 1991b). The AgNOR technique (Smith & Crocker, 1988) permits the estimation of proliferative activity and clinical behaviour of several malignancies by means of light microscopy (Crocker et al., 1989).

In bladder cancer the results presented until now are controversial in terms of survival and progression (Cairns et al., 1989; Ooms & Veldhuizen, 1989; Mansour et al., 1990; Lipponen & Eskelinen, 1991a). To establish the predictive value of AgNORs in bladder cancer a series of 229 patients with a bladder cancer followed up for over 10 years was analysed using AgNOR method (Smith & Crocker, 1988). Moreover, the relationship between DNA index (DI), S-phase fraction (SPF) and AgNORs was assessed.

Patients and methods

Patients, treatment and follow-up

The study comprised patients with a newly diagnosed transitional cell bladder cancer at Kuopio University Hospital in 1965–1989. TIS tumours (UICC, 1978) were not included. The follow-up analysis was done in January 1990 and the mean (s.d.) observation time was 10.5 (3.9) years (Range 4–24). In total there were 229 patients of ages 45–84 years (mean (s.d.), 66.1 (12.6)) the female/male ratio being 46/183. Occasionally patients were excluded from the series because of insufficient follow-up histories, missing or insufficient pretreatment biopsy specimens. The treatment and follow-up investigations were done according to uniform guidelines (Zingg & Wallace, 1985). Superficial tumours were treated by transurethral resection and prophylactic intravesical chemotherapy was used in 39 cases. The clinical staging of tumours was based on results of intravenous pyelography, transurethral biopsy, cytological examination and bimanual palpation under anesthesia. In many of muscle invasive tumours during the latest years a computerised tomography or ultrasound examination was done. Screening for metastases included chest radiography, laboratory tests, abdominal ultrasound, and when appropriate, bone scintigraphy and lymphography. TNM classification of tumours was done according to UICC (UICC, 1978). The follow-up investigations were done at 3 month intervals during the first 2 years and thereafter at 6 month intervals (Zingg & Wallace, 1985). The recurrence free period (RFP) was defined as the time from primary treatment to the first observed recurrence in the bladder. Recurrence rate (RR) was calculated as the number of recurrences divided by months of follow-up × 100. The majority of patients who died were autopsied to ascertain the extent and metastasis of tumours.

Histological grading

Pretreatment biopsy specimens from the primary tumours were fixed in buffered formalin (pH = 7.0), embedded in paraffin, sectioned at 5 μm and stained with haematoxylin and eosin. The grading was done by a board certified pathologist according to WHO (Mostofi, 1973). The growth pattern of tumours was recorded and the tumours were divided into papillary or non-papillary nodular types. The distribution of patients into WHO grade and clinical stage categories is shown in Table I.

Staining for AgNORs

The method described by Smith and Crocker (Smith & Crocker, 1988) was used. In brief, 5 μm thick sections were cut from paraffin embedded biopsy specimens, dewaxed in

Received 26 March 1991; and in revised form 24 July 1991.
xylene (5 min) and rehydrated through ethanol to distilled deionised water. The AgNOR solution was made by dissolving gelatine in 1 g dl aqueous formic acid at concentration of 2 g dl. This solution was mixed (1:2) with 50 g dl aqueous silver nitrate solution which was the final solution used in staining procedure. A staining time of 38 min was used. The optimal staining time was tested before the whole series was stained (Lipponen & Eskelinen, 1991a). For counting the AgNORs the section were examined under an oil immersion lens at a magnification of 1000 × . The areas of most atypical histology were analysed avoiding sample margins and necrotic areas. In every section 70 nuclei were examined in the centres of seven fields, ten neighbouring nuclei in each. The maximum number of AgNORs visible at the same time within the nucleus was recorded by focusing the microscope. AgNORs were identified as recommended by Crocker et al. (Crocker et al., 1989) by counting all silver stained structures when could be clearly resolved within a cluster as well as AgNORs lying free within the nucleoplasm. In the present analysis the mean number of AgNORs/nucleus is used. The AgNORs in normal peri vesical lymph node and in WHO grade III tumour are shown in Figures 1a and b. The AgNORs were counted twice in 15 random samples and the intraobserver error was < 5%.

Flow cytometry

The method and results have been reported previously except data related to recurrences. The reader is referred to original text (Lipponen et al., 1991b) for details. Tumours with a DNA index < 1.05 were considered diploid.

Statistical methods

SPSS/PC + V3.1 program package were used in a Toshiba T3200 computer. In survival analysis life-table method was used with Lee-Desu statistics (Lee & Desu, 1972). In the first analysis all cases were included whereas the second analysis included papillary tumours alone. In the third analysis Ta-T1 and T2-T3 tumours were separately analysed. In addition, the predictive value of AgNORs was assessed within WHO grades and within DNA ploidy groups. The numerical data is expressed as mean( ± S.E.). The specific test used in comparing the differences are indicated when appropriate.

Results

All cases

The number of AgNORs was significantly related to clinical stage, papillarity, WHO grade, DNA ploidy and 5-phase fraction (Table II). Twenty-six tumours with pelvic lymph node metastasis at the time of diagnosis had more AgNORs, 3.8 (0.3) than tumours confined to bladder wall (n = 203), 3.0 (0.9), (P = 0.0085). Seven tumours with distant metastasis had higher numbers of AgNORs, 4.0 (0.8), than tumours without metastasis, 3.0 (0.9), (P = 0.078). Progressing tumours (T- , N- and M-categories) had significantly more AgNORs than non-progressing ones (Table III). Non-progressing (T) WHO grade III tumours (n = 25) had lower numbers of AgNORs, 3.9 (0.3) than progressing tumours (n = 21), 4.9 (0.4), (P = 0.0711) whereas grade I-II tumours could not be re-grouped. In a logistic multivariate regression analysis AgNORs predicted progression independently (Table IV). RR and RFP were related significantly to AgNOR count (Table V). Diploid tumours with high numbers of AgNORs had shorter RFPs than tumours with low numbers of AgNORs (Table V) whereas aneuploid tumours could not be re-grouped. Tumours leading to cancer death had higher numbers of AgNORs than non-fatal tumours (Table VI). In survival analysis AgNORs predicted disease related survival (Table VI, Figure 2) and diploid tumours could be subdivided according to AgNORs (Figure 3). In multivariate survival analysis including clinical stage, WHO grade, papillarity and FCM variables AgNORs had no independent predictive value.

Papillary tumours

AgNORs were related to clinical stage (P = 0.0021), WHO grade (P < 0.0001), DNA ploidy (P = 0.0140) and SPF (P = 0.0007) as seen in Table II. Progression in T-, N- and M-categories was related to AgNORs (T; P = 0.0110, N; P = 0.0190, M; P = 0.0110). Non-progressing (T) tumours (n = 140) had a mean of 2.6 (0.9) AgNORs whereas 3.2 (0.2) AgNORs was present in progressing tumours. AgNORs predicted independently progression in a multivariate analysis.

Table I The distribution of 229 patients into WHO grade and clinical stage categories

| Histological grade | Clinical stage | Ta | T1 | T2 | T3 | T4 | Total |
|--------------------|---------------|----|----|----|----|----|-------|
| I                  |               | 3  | 61 | 13 | 4  | 2  | 83    |
| II                 |               | 45 | 34 | 16 | 5  |    | 100   |
| III                |               | 11 | 13 | 12 | 10 |    | 46    |
| Total              |               | 3  | 117| 60 | 32 | 17 | 229   |

Figure 1 Normal lymphocytes in a peri vesical lymph node a, having one to two AgNORs within each nucleus. In WHO grade III bladder tumour b, numerous dispersed AgNORs and clusters of AgNORs can be seen within each nucleus.

Papillary tumours

AgNORs were related to clinical stage (P = 0.0021), WHO grade (P < 0.0001), DNA ploidy (P = 0.0140) and SPF (P = 0.0007) as seen in Table II. Progression in T-, N- and M-categories was related to AgNORs (T; P = 0.0110, N; P = 0.0190, M; P = 0.0110). Non-progressing (T) tumours (n = 140) had a mean of 2.6 (0.9) AgNORs whereas 3.2 (0.2) AgNORs was present in progressing tumours. AgNORs predicted independently progression in a multivariate analysis.
Table II The mean (s.e.) values of AgNORs subdivided according to T-category, papillarity, WHO grade, DNA ploidy and SPF

| Category          | Number | AgNOR (s.e.) | P-value |
|-------------------|--------|--------------|---------|
| T-category        |        |              |         |
| Ta                | 3      | 2.6 (0.3)    |         |
| T1                | 117    | 2.8 (0.1)    |         |
| T2                | 60     | 3.2 (0.1)    | 0.0111* |
| T3                | 32     | 3.7 (0.3)    |         |
| T4                | 17     | 3.5 (0.4)    |         |
| Papillarity       |        |              |         |
| Papillary         | 190    | 2.8 (0.1)    | <0.0001 |
| Non-papillary     | 39     | 4.3 (0.3)    |         |
| WHO grade         |        |              |         |
| I                 | 83     | 2.4 (0.1)    |         |
| II                | 100    | 3.0 (0.1)    | <0.0001*|
| III               | 44     | 4.4 (0.3)    |         |
| DNA ploidy        |        |              |         |
| Diploid           | 129    | 2.8 (0.1)    |         |
| Aneuploid         | 72     | 3.6 (0.2)    | 0.0010  |
| SPF < 10.0%       | 114    | 2.7 (0.1)    |         |
| SPF > 10.0%       | 61     | 3.7 (0.2)    | <0.0001 |

Table III The mean (s.e.) numbers of AgNOR in progressing and non-progressing bladder tumours

| Progression       | Number | AgNOR (s.e.) | P-value |
|-------------------|--------|--------------|---------|
| T-category        |        |              |         |
| No progression    | 163    | 2.8 (0.1)    |         |
| Progression       | 66     | 3.6 (0.2)    | 0.0030  |
| N-category        |        |              |         |
| No progression    | 162    | 2.8 (0.1)    |         |
| Progression       | 67     | 3.6 (0.2)    | 0.0010  |
| M-category        |        |              |         |
| No progression    | 159    | 2.8 (0.1)    |         |
| Progression       | 70     | 3.6 (0.2)    | 0.0010  |

*Student’s t-test.

Table IV The results of logistic multiparameter regression analysis of progression in T-category

| Category          | \(\hat{\beta}\) | s.e. | Significance |
|-------------------|-----------------|------|--------------|
| All cases (n = 175) | 0.3090          | 0.1222 | 0.0115      |
| AgNOR             | 0.0422          | 0.0191 | 0.0273      |
| Papillary tumours (n = 146) | 0.0631   | 0.0219 | 0.0040      |
| To-T1 tumours (n = 93) | 0.3999   | 0.1667 | 0.0165      |

The analysis included T-category, WHO grade, papillarity, DNA index (DI), SPF and the number of AgNORs. The independent predictors at significance level of <0.055 are only shown. \(\hat{\beta}\) = beta coefficient of regression model; s.e. = standard error \(\hat{\beta}\).

Table V The recurrence-free period (RFP) (years) in all cases (n = 229), in papillary tumours (n = 190), and in diploid tumours (n = 129) subdivided according to number of AgNORs

| Category          | Number | RFP (s.e.) | P-value |
|-------------------|--------|------------|---------|
| All cases         |        |            |         |
| AgNOR ≤ 3.5       | 160    | 4.2 (0.3)  |         |
| AgNOR > 3.5       | 69     | 2.5 (0.4)  | 0.0010  |
| Papillary tumours |        |            |         |
| AgNOR ≤ 3.5       | 146    | 4.4 (0.4)  |         |
| AgNOR > 3.5       | 44     | 2.8 (0.5)  | 0.0125  |
| Diploid tumours   |        |            |         |
| AgNOR ≤ 3.5       | 103    | 4.4 (0.4)  |         |
| AgNOR > 3.5       | 26     | 2.3 (0.6)  | 0.0045  |
| SPF               |        |            |         |
| SPF ≤ 10.0%       | 127    | 4.1 (0.4)  |         |
| SPF > 10.0%       | 66     | 2.3 (0.4)  | 0.0010  |

*Student’s t-test. For comparison the RFP subdivided according to SPF is shown.

Figure 2 Disease related survival of all patients subdivided according to number of AgNORs. The difference in survival between curves is significant (\(p^2 = 12.1, P = 0.0005\)). Curve A: n = 160, AgNOR number ≤ 3.5; Curve B: n = 69, AgNOR number > 3.5.

(Table IV). AgNORs were related to RFP (Table V) whereas the RR could not be predicted by AgNORs. WHO grade (\(P = 0.0582\)), DNA ploidy (\(P = 0.0261\)) and SPF (\(P = 0.0747\)) were related to RFP. AgNORs predicted disease related survival significantly (Table VI, Figure 4). In multivariate analysis AgNORs had no independent predictive value.

Ta-T1 and T2-T3 tumours

A significant relationship between AgNOR count, papillarity (\(P = 0.0060\)), WHO grading (\(P < 0.0001\)), DNA ploidy (\(P = 0.0700\)) and SPF (\(P = 0.0028\)) was present. Progression in T-(\(P = 0.12\)) and SPF (\(P = 0.18\)) were related to AgNORs with a borderline significance. In a logistic multiparameter analysis AgNORs had independent prognostic values as predictors of progression (Table IV). The RR (\(P = 0.12\)) and SPF (\(P = 0.18\)) were related to AgNORs with a borderline significance. WHO grade (\(P = 0.118\)), DNA ploidy (\(P = 0.069\)), SPF (\(P = 0.065\)) and papillarity (\(P = 0.098\)) predicted RFP. DNA ploidy (\(P = 0.0370\)) and SPF (\(P = 0.0500\)) were significant predictors of RR. In diploid tumours the RR was 2.5 (0.4) vs 5.1 (1.1) of aneuploid tumours (\(n = 26\)). Tumours with SPF ≤ 15.0% had a mean RR of 2.6 (0.4) in comparison to 10.4 (3.0) in tumours with SPF >15.0%. In diploid tumours AgNORs predicted RFP to some degree (\(P = 0.20\)). In univariate survival analysis...
AgNORs predicted disease related survival (Figure 5) whereas in multivariate analysis they had no independent predictive value.

In T2-T3 tumours AgNORs predicted progression in univariate analysis ($P = 0.0410$) whereas they had no independent predictive value in multivariate analysis. Non-progressing tumours ($T$) ($n = 49$) had $3.0 (0.2)$ AgNORs whereas progressing tumours ($n = 43$) had a mean of $3.7 (0.2)$ AgNORs. AgNORs predicted bladder cancer related survival in univariate analysis ($\chi^2 = 11.1, P = 0.004$). In a multivariate analysis they had no independent predictive value.

Discussion

The present series has previously been analysed by morphometry (Lipponen & Eskelinen, 1990a, 1990b; Lipponen et al., 1990c) and DNA flow cytometry (Lipponen et al., 1991a). The predictive value of clinical stage, papillarity and WHO grade has been described in connection with these reports. So, special emphasis is given to AgNORs which are subject to controversies as prognostic variables or indicators of proliferative activity in several malignancies (Giri et al., 1989; Rushoff et al., 1990a; Sivridis & Sims, 1990; Delahut et al., 1991; Eskelinen et al., 1991b) including transitional cell bladder cancer (Cairns et al., 1989; Ooms & Veldhuizen, 1989; Mansour et al., 1990; Lipponen & Eskelinen, 1991a).

The AgNORs are located in acrocentric chromosomes, each chromosome having two AgNORs. All AgNORs are not visible in normal histological sections and usually one or two may be present within the nucleus (Underwood & Giri, 1988). Accordingly 20 AgNORs may be visible in normal nucleus before mitosis. Since in aneuploid cells the number of chromosomes at any phase of cell cycle is higher than in diploid cells higher AgNOR counts can be found in case additional chromosomal material bears NOR sites. However, AgNORs present active rRNA (Wachler et al., 1986) and the proliferative activity of a given cell determines the number of AgNORs suggesting a relationship between the number of AgNORs and SPF.

Aneuploid tumours as well as tumours with high SPF had significantly higher numbers of AgNORs than diploid tumours with low SPF. The results are in agreement with the results in breast tumours (Giri et al., 1989; Eskelinen et al., 1991b). Consequently, high grade tumours, non-papillary tumours and muscle invasive tumours had higher AgNOR counts since most of these tumours are aneuploid (Lipponen et al., 1991b). The relationship between grade, papillarity and AgNOR counts has been presented previously (Cairns et al., 1989; Ooms & Veldhuizen, 1989; Lipponen & Eskelinen, 1991a) the present results supporting these findings. The relationship between DNA flow cytometric data and AgNORs has not been reported previously in transitional cell bladder tumours.

The AgNORs were able to predict pelvic lymph node involvement at the time at diagnosis as well as they predict...
auxiliary lymph node involvement in breast cancer (Sivridis & Sims, 1990). The potential of AgNORs to predict pretreatment lymph node metastasis is similar to that of DNA ploidy and SPF in the same clinical material (Lipponen et al., 1991b). Moreover, AgNORs were related significantly to progression postoperatively the results being in line with those obtained by mitotic indexes (Lipponen & Eskelinen, 1990b, Lipponen et al., 1990c) and DNA flow cytometry (Lipponen et al., 1991b). The potential to predict progression in Ta-T1 tumours may permit a more precise stratification of these tumours like mitotic indexes (Lipponen et al., 1990c) or flow cytometric data (Lipponen et al., 1991b). WHO grading seems to be of rather limited value in predicting progression in individual cases (Lipponen et al., 1990c). This is supported by the ability of AgNORs to regroup WHO grade III tumours in terms of progression. These latter results are contradictory to observations presented previously (Mansour et al., 1990), however, their series included 11 patients with a short follow-up.

Aneploid bladder tumours with high SPF recur more often having usually a shorter RFP than diploid ones (Blomjous et al., 1989) whereas WHO grade is a weak predictor of RFP (Lipponen & Eskelinen, 1990a). In the present analysis AgNORs predicted REF like SPF, DNA index or mitotic activity (Lipponen et al., 1990c). It was unexpected that RFP of diploid tumors could be further regrouped according to their AgNOR number. This latter finding may be related to intratumour heterogeneity of DNA ploidy (Lipponen et al., 1991b) or AgNORs are independent of DNA ploidy since the proliferative status of a given cell determines the AgNOR number (Wachtler et al., 1986). Aneploid tumours could not be regrouped, however. The relationship between AgNORs and RFP in bladder cancer is consonant to results in breast cancer in which AgNORs predict significantly RFP, too (Eskelinen et al., 1991b). The differences in RR and RFP could not be attributed to intravesical chemotherapy since it had not significant predictive value in univariate analysis ($P = 0.213$) or in multivariate analysis.

AgNORs were related to progression consequently predicting disease related survival. In colon tumours (Rushoff et al., 1990a; Ööner et al., 1990) and in renal cell tumours (Delahut et al., 1991), AgNORs have been able to predict survival significantly even within clinical stage categories (Delahut et al., 1991). Accordingly, AgNORs predicted survival in papillary bladder tumours, in superficial tumours and in muscle invasive tumours. Surprisingly, diploid bladder cancers could be stratified. As with recurrences, this latter result is with a higher probability related to intratumour heterogeneity of DNA ploidy (Lipponen et al., 1991b). On the other hand, SPF can regroup diploid tumours which suggest subgroups of diploid bladder tumours with different proliferative potentials. Patients dying of their bladder cancer had higher AgNOR counts than patients dying of intercurrent diseases or being alive after follow-up. However, in a multivariate analysis of survival including clinical, histological, flow cytometric variables and AgNORs, the AgNORs had no independent prognostic value.

The methodology in the present analysis differs from that of many other analyses presented until now (Cairns et al., 1989; Mansour et al., 1990; Lipponen & Eskelinen, 1991a). Firstly, the areas of analysis were selected aiming at finding the most atypical fields for measurement whereas previous studies have used random sampling. We feel that selective sampling led us to improved predictive results. The importance of selection of fields for analysis cannot be over emphasised since bladder tumours often show intratumour heterogeneity of malignancy (Lipponen et al., 1991b). In accordance with the above selective morphometry (Lipponen & Eskelinen, 1990a, Lipponen & Eskelinen, 1990b) has given good prognostic results in bladder cancer. Secondly, 3 μm thick sections were used in contrast to 3 μm thick sections were used in contrast to 3 μm sections used in most studies. In 3 μm sections dispersed AgNORs free within the nucleus may be lost and the data are 'compressed' between high- and low-count specimens (Crocker et al., 1989). In the present analysis the microscope was focused to find the maximum number of AgNORs visible at the same time. The number of nuclei counted was limited to 70 since the counting of AgNORs is time consuming and moreover the methodological studies have shown that the standard error of the mean does not vary significantly after 50–60 nuclei has been counted (Rushoff et al., 1990b). In the present analysis the intraobserver variation of the mean was 5% which is comparable to results observed by other researchers (Mansour et al., 1990; Rushoff et al., 1990b; Sivridis & Sims, 1990).

From the results we can conclude that AgNORs are related to proliferative activity and malignancy in bladder cancer. AgNORs have independent prognostic value in superficial bladder tumours as predictors of progression. In muscle invasive tumours classic prognostic factors and flow cytometric variables are more important predictors. The results suggest that AgNORs can be used as an adjunct to histological grading, flow cytometry and mitotic indexes in predicting clinical behaviour in superficial bladder tumours. It is hard to imagine the use of AgNORs alone in predicting individual cases of bladder cancer due to considerable overlap in AgNOR counts between malignant and more benign bladder tumours. The results encourage for further studies giving special emphasis to standardisation of measurement process and this refers to morphometric methods, in particular (Rushoff et al., 1990a; Rushoff et al., 1990b). The study was supported by a research grant from Savon Suipäärasto. The assistance of Mrs A.-L. Gidlund is gratefully acknowledged.
