ABSTRACT

We present H i observations of the edge-on galaxy NGC 891. These are among the deepest ever performed on an external galaxy. They reveal a huge gaseous halo, much more extended than seen previously and containing almost 30% of the H i. This H i halo shows structures on various scales. On one side, there is a filament extending (in projection) up to 22 kpc vertically from the disk. Small (\(M_{\text{HI}} \gtrsim 10^6\,M_\odot\)) halo clouds, some with forbidden (apparently counterrotating) velocities, are also detected. The overall kinematics of the halo gas is characterized by differential rotation lagging with respect to that of the disk. The lag, more pronounced at small radii, increases with height from the plane. There is evidence that a significant fraction of the halo is due to a galactic fountain. Accretion from intergalactic space may also play a role in building up the halo and providing the low angular momentum material needed to account for the observed rotation lag. The long H i filament and the counterrotating clouds may be direct evidence of such accretion.

1. INTRODUCTION

Recent deep observations of the neutral hydrogen of several nearby spiral galaxies indicate that up to about 15% of the neutral hydrogen of a spiral galaxy is located in the halo. The best examples are NGC 891 (Swaters et al. 1997), NGC 2403 (Schaap et al. 2000; Fraternali et al. 2001), NGC 4559 (Barbieri et al. 2005), M31 (Westmeier et al. 2005), UGC 7321 (Matthews & Wood 2003), NGC 253 (Boomsma et al. 2005b), NGC 5775 (Lee et al. 2001), and NGC 6946 (Boomsma et al. 2005a; Boomsma 2007). Overall, the kinematics of the halo gas is quite regular. The main motion is differential rotation parallel to the plane. However, the rotation velocities in the halo are lower than in the disk (Swaters et al. 1997; Fraternali et al. 2002). In some cases a small overall radial inflow is found superposed on the rotation (Fraternali et al. 2001). On small scales strong vertical motions from and toward the disk are also observed (Boomsma et al. 2005a; Boomsma 2007). Halo gas is also detected in H\(\alpha\) (e.g., Hoopes et al. 1999; Rossa & Dettmar 2003), with kinematics similar to that of the neutral gas (Rand 2000; Tüllmann et al. 2000; Fraternali et al. 2004; Heald et al. 2006b, 2007; Kamphuis et al. 2007), and in X-rays (e.g., Strickland et al. 2004).

The origin of the gaseous halos is still a matter of debate. The galactic fountain mechanism (Shapiro & Field 1976) has received the most attention to date. In this scheme, gas is pushed into the halo by stellar winds and supernova explosions, mostly in the hot ionized phase. This gas travels through the halo, eventually cools to neutral, and falls back to the disk (Bregman 1980). There is strong observational evidence supporting the fountain mechanism, such as the close correlation between the distribution of H\(\alpha\) and the high-velocity gas found in NGC 6946 (Boomsma 2007), as well as that the star formation rate appears to correlate with the luminosity of the X-ray halo (Tüllmann et al. 2006a) and with the radio continuum emission of the halo (Dahlem et al. 2006). However, the sample of galaxies studied so far is still too small to be able to make any statement on whether flows related to star formation are the dominant mechanism or not, in particular for the neutral halos. Furthermore, there are indications that an ionized halo only builds up if the star formation rate is above a critical value (Tüllmann et al. 2006a), which may pose a problem for the H i halo detected in the superthin LSB galaxy UGC 7321, a galaxy with a low star formation rate (Matthews & Wood 2003). The main problem for the fountain mechanism comes, however, from the study of the kinematics. Simple (i.e., so-called ballistic) models have been unable to reproduce the kinematics of the ionized gas (Collins et al. 2002; Heald et al. 2006b). Recently, Fraternali & Binney (2006) have also shown that the kinematics of the neutral halo gas cannot be explained by “pure” ballistic galactic fountains. This suggests that other effects, such as interaction with a pre-existing hot halo or accretion from intergalactic space, must play an important role. There have also been attempts to model the extraplanar gas as a stationary medium in hydrostatic equilibrium (Benjamin 2002; Barnabé et al. 2006) or as a cooling flow accretion in a CDM context (Kaufmann et al. 2006), but none of these models is able to reproduce the observations completely. It is possible that the halo gas is the result of complex phenomena involving both internal and external processes.

Understanding the origin and nature of the gaseous halos surrounding spiral galaxies is important for several reasons. First,
the halo is the region where material can be exchanged between different parts of the galaxy, and this circulation of gas is fundamental to the galactic life cycle. Second, galactic halos are the interface between the galaxy, which is visible and well studied, and the intergalactic medium (IGM), the content and properties of which remain largely unknown. CDM cosmological models predict that most of the baryonic material is currently in the IGM (e.g., White & Frenk 1991; Sommer-Larsen 2006). The discovery of the halo gas may provide a new and efficient way to probe the IGM by studying the exchange of material between galaxies and their environment.

We believe that the halo gas observed in external galaxies is the analog of the intermediate- and high-velocity clouds (IVCs and HVCs) of the Milky Way (Wakker & van Woerden 1997). The cloud complexes with anomalous velocities found in galaxies like NGC 2403 (Fraternali et al. 2002) have similar masses and velocity deviations with respect to the disk as the largest galactic HVCs for which the distances are known (e.g., complex A; Wakker 2001). The total gas mass of the HVCs, if located in the halo at distances up to a few tens of kiloparsecs, would be on the order of $10^8 M_\odot$. Similar to that of the H I found in the halos of external galaxies (e.g., NGC 891, Swaters et al. 1997; NGC 2403, Fraternali et al. 2002). It is therefore interesting to note that some of the HVCs, in particular complex C, have been found to have a low metallicity ($Z \sim 0.1-0.3 Z_\odot$; Tripp et al. 2003). This may indicate that some of the HVCs are accretion from the surrounding IGM of “unprocessed” material onto the disk of our Galaxy. Such accretion may be necessary to explain the evolution of disk galaxies (Naub & Ostriker 2006). Accretion onto disk galaxies may also occur as the merging of small, gas-rich satellites (van der Hulst & Sancisi 1988, 2005). Recently, a search has been carried out toward the two largest members of the Local Group other than the Milky Way, M31 and M33 (Westmeier et al. 2005), and a population of high-velocity clouds at large distances from these galaxies (about 50 kpc from M31; Thilker et al. 2004) has been found. These clouds have typical masses of a few $10^5 M_\odot$. Most of them are thought to be remnants of the accretion of small companion galaxies, although a small fraction might be primordial gas clouds (Westmeier et al. 2005).

In this paper we present very deep H I observations of the nearby edge-on spiral galaxy NGC 891 obtained with the upgraded Westerbork Synthesis Radio Telescope (WSRT). NGC 891 is an Sh/SBb galaxy, one of the best studied nearby edge-on galaxies. The disk of NGC 891 shows intensive star formation at a rate of $\sim 3.8 M_\odot$ yr$^{-1}$ (Popescu et al. 2004). The halo region has been studied at various wavelengths and shows a variety of components from radio continuum emission (e.g., Allen et al. 1978) to hot diffuse gas (e.g., Bregman & Pildis 1994). NGC 891 is considered to be very similar to the Milky Way with regard to mass and stellar components (van der Kruit 1984), although it has a higher star formation rate and significantly stronger radio continuum emission. A summary of its physical parameters is given in Table 1.

In the past, NGC 891 has been studied in H I several times with ever-increasing sensitivity (e.g., Sancisi & Allen 1979; Rupen 1991; Swaters et al. 1997). The first indication of extraplanar material had been reported already by Sancisi & Allen (1979), but their favored explanation was that of a flaring outer disk. Almost two decades later, Becquaert & Combes (1997) proposed a different interpretation in terms of a warp of the H I disk along the line of sight. Finally, more sensitive WSRT observations of NGC 891 revealed a much more extended extraplanar component (Swaters et al. 1997), and a careful modeling of the full data cube showed that the most likely explanation was that of an extended halo component rotating more slowly than the disk. Here we report the results of H I observations that are a factor 5 more sensitive than those of Swaters et al. (1997). These observations reveal that the gaseous halo is much more extended than shown by the previous data.

### 2. OBSERVATIONS

The present observations were obtained with the WSRT in the period 2002 August–December. In total, 20 complete 12 hr observations were performed, using five of the standard array configurations. The combination of these different configurations gives a regular sampling of the $u$–$v$ plane from the shortest spacing of 36 m to the longest baseline of 2754 m, with an interval of 36 m. Care was taken not to use data affected by solar interference that might have compromised the detection of faint, extended emission from the halo. The effective integration time corresponds to that of 17 complete 12 hr observations. The observing bandwidth is 10 MHz (corresponding to about 2000 km s$^{-1}$), using 1024 channels (with two independent polarizations). An overview of the observational parameters is given in Table 2. The data processing was done using the MIRIAD package (Sault et al. 1995). Before and after each 12 hr observation, a standard

### TABLE 1

**Optical and Radio Parameters for NGC 891**

| Parameter                        | Value  |
|----------------------------------|--------|
| Morphological type              | Sh/SBb |
| Radio continuum center $\alpha$ | $(2000.0)$ | 2 22 33.0 |
| Radio continuum center $\delta$ | $(2000.0)$ | 42 20 57.2 |
| Distance (Mpc)                  |         | 9.5 |
| $LS(L_d)$                       |        | $2.6 \times 10^{10}$ |
| Scale length stellar disk (kpc) |         | 4.4 |
| SFR ($M_\odot$ yr$^{-1}$)       |         | 3.8 |
| Systemic velocity (km s$^{-1}$) |         | 528 ± 2 |
| Total H I mass ($M_\odot$)      |         | $4.1 \times 10^{9}$ |
| H I inclination (deg)           |         | $\geq 89$ |
| Mean P.A. (no warp) (deg)       |         | 23 3 |
| Total mass ($M_\odot$)          |         | $1.4 \times 10^{11}$ |

**Notes:** Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds.

### TABLE 2

**Observational Parameters for NGC 891**

| Parameter                                      | Value  |
|-----------------------------------------------|--------|
| Observation dates                             | 2002 Aug–Dec |
| Total length of observation (hr)              | $20 \times 12$ |
| Effective integration time (hr)               | 204  |
| Pointing $\alpha$ (J2000.0)                   | 2 22 33.76 |
| Pointing $\delta$ (J2000.0)                   | 42 20 57.1 |
| Velocity center of band (km s$^{-1}$)         | 800    |
| Total bandwidth (MHz)                         | 10     |
| Total bandwidth (km s$^{-1}$)                 | $\sim 2000$ |
| Number of channels in observation             | 1024   |
| Channel separation in observation (kHz)       | 9.77   |
| Channel separation of final data cube (kHz)   | 224    |
| Velocity resolution (after Hanning) (km s$^{-1}$) | 38.5 |

**Note:** Units of right ascension are hours, minutes, and seconds, and units of declination are degrees, arcminutes, and arcseconds.

The present observations were obtained with the WSRT in the period 2002 August–December. In total, 20 complete 12 hr observations were performed, using five of the standard array configurations. The combination of these different configurations gives a regular sampling of the $u$–$v$ plane from the shortest spacing of 36 m to the longest baseline of 2754 m, with an interval of 36 m. Care was taken not to use data affected by solar interference that might have compromised the detection of faint, extended emission from the halo. The effective integration time corresponds to that of 17 complete 12 hr observations. The observing bandwidth is 10 MHz (corresponding to about 2000 km s$^{-1}$), using 1024 channels (with two independent polarizations). An overview of the observational parameters is given in Table 2. The data processing was done using the MIRIAD package (Sault et al. 1995). Before and after each 12 hr observation, a standard
calibrator was observed (J2052+365 and 3C 147) from which the spectral response of the telescope was determined. As is standard practice with the WSRT, during each 12 hr track no additional (phase) calibrators were observed to monitor the time variation of system properties. Instead, the large bandwidth allows the determination of these by self-calibration of the continuum image made from the line-free channels of the data. This self-calibration was done using a model of the continuum emission based on the combination of all observations. An advantage of this approach is that it also gives an excellent removal of the continuum sources in the line images, as well as a well-calibrated continuum image (see § 3.4).

Three data cubes were made with three spatial resolutions: 23.4" × 16.0", 33.2" × 23.9", and 69.6" × 58.9" (see Table 3). The line data were combined and gridded into cubes of 224 channels 8.2 km s⁻¹ wide, to which additional Hanning smoothing was applied. This resulted in a velocity resolution of 16.4 km s⁻¹.

As always with radio observations, the highest-resolution data set has the lowest noise level (0.09 mJy beam⁻¹); the 30" and 60" data sets have noise levels of 0.10 and 0.12 mJy beam⁻¹, respectively. The 3σ detection limits over one resolution element in the plane, we find that the H i in the halo represents 29% (1.2 × 10⁴ M☉) of the total H i content of NGC 891. As one can see from the lowest contours, the difference in sensitivity between our total H i map and that of Swaters et al. (1997) is about a factor of 5. The H i observations presented here are among the deepest ever obtained for an external spiral galaxy. It is therefore quite possible that other galaxies, if observed with comparable high sensitivity, would also show similar extended extraplanar emission, and gaseous halos may be a common feature among spiral galaxies.

The vertical extent of the H i layer is illustrated in Figure 2, where we plot the normalized average H i column density, based on the 30" data set, for the four quadrants of the galaxy. In the northeast, southeast, and southwest quadrants the H i halo extends out to about 5′ (14 kpc), while in the northwest quadrant it extends even further out, to about 8′ (~22 kpc). The density profiles in the northeast, southeast, and southwest quadrants are very similar and can be modeled quite well with an exponential profile with a scale height of 50″ (~2.2 kpc). In the northwest quadrant the density distribution seems to follow the same trend out to about 3′ (8.3 kpc), after which it becomes flatter. This larger extent in the northwest quadrant corresponds to a large filament extending out to more than 20 kpc from the disk (see Fig. 1).

Around the northwest filament a crowd of high-latitude clouds are observed (Figs. 3 and 4), which are probably associated with the filament itself. However, individual gas clouds are also observed at large radii and at very anomalous velocities (with large deviations from rotation). The middle panels of Fig. 4 show two of these clouds at “apparently” counterrotating velocities. The first is in the northwest quadrant at velocities that differ by about 100 km s⁻¹ from the velocity of the halo at that position. This cloud is probably located in the outskirts of the halo; otherwise, the drag force of the halo would invert its motion very quickly. The second cloud is detected (Fig. 4, middle right) at a projected distance of about 28 kpc from the center of the galaxy. These clouds have masses of M_1 ≈ 1–3 × 10⁴ M☉.

As stated above, the new data do not reveal significant new features at large radii in the plane of the disk. As the earlier data showed, the H i disk of NGC 891 is not symmetric, being more extended on the southwest side. The falloff and disappearance of the H i disk on the northern side of NGC 891, approximately coincident with the end of the stellar disk, and the large southern extension confirm the picture of lopsidedness already known from previous observations and discussed by Baldwin et al. (1980).

### Table 3: Parameters of the Data Cubes

| Parameter                                          | Full Resolution | Intermediate Resolution | Low Resolution |
|-----------------------------------------------------|----------------|-------------------------|---------------|
| Spatial resolution (arcsec)                         | 23.4 × 16.0     | 33.2 × 23.9             | 69.6 × 58.9   |
| P.A. of synthesized beam (deg)                      | 12.3            | 16.0                    | 16.0          |
| Beam size (kpc)                                     | 1.08 × 0.74     | 1.53 × 1.09             | 3.2 × 2.7     |
| rms noise per channel (mJy beam⁻¹)                  | 0.090           | 0.10                    | 0.12          |
| Minimum detectable column density (3σ cm⁻²)         | 13.0 × 10¹⁸     | 6.8 × 10¹⁸              | 1.6 × 10¹⁸    |
| Minimum detectable mass (3σ; M_☉ per resolution element) | 9.3 × 10⁹      | 1.0 × 10⁹              | 1.3 × 10⁹    |

1 We assume a distance to NGC 891 of 9.5 Mpc (van der Kruit 1981); l′ corresponds to 2.76 kpc.
However, the fact that, despite the large improvement in sensitivity, NGC 891 does not grow in radius but does grow substantially in the vertical direction poses an interesting question. The presence and the origin of outer cutoffs of H\textsubscript{i} disks have been a matter of debate in the past years. One of the favored explanations for their origin has been the effect of the extragalactic radiation field (Maloney 1993). In the case of NGC 891, such an explanation would immediately encounter a serious objection: why would the H\textsubscript{i} be ionized by a presumably isotropic radiation field in the plane of the galaxy (and account for the northern truncation) and apparently not be affected at all in the low-density halo regions? Unless the timescales for the disk and for the halo gas and for their respective ionizations are significantly different, it seems more likely that the disappearance of H\textsubscript{i} on the northern side of NGC 891 simply marks the outer boundary of the gaseous disk.

### 3.2. Kinematics

The kinematics of the H\textsubscript{i} gas is shown by the position-velocity (p-V) diagrams parallel and perpendicular to the disk (Figs. 3 and 5). In these diagrams, the high-resolution data are shown with thin contours and gray scale, while the thick contours show the low-resolution (60\textquoteleft) data at a 3\sigma level. The low resolution is intended to outline the full extent of the faint emission. The top panel in Figure 5 shows the distribution along the major axis (i.e., in the plane) of NGC 891. The rotation curve is shown by the squares and crosses in Figure 6. This has been derived by tracing the "envelope," as already done and described by Sancisi & Allen (1979) and using a gas velocity dispersion of 8 km s\textsuperscript{-1}. This method is also used by F. Fraternali (2007, in preparation) to derive the rotation curves for the halo gas of NGC 891 at various distances from the plane. As already mentioned, the disk of NGC 891 is lopsided, being more radically extended on the receding southwest side. The rotation in the plane is characterized by an inner peak produced by a fast-rotating inner ring or by a bar (Garcia-Burillo & Guelin 1995). This feature is symmetric with respect to the center and also with respect to the systemic velocity. Beyond this, the disk is clearly dominated by differential rotation, showing a roughly flat rotation curve out to a distance of about 6\textquoteleft (~17 kpc) from the center (Fig. 6). The receding side extends further out, with an apparent decrease in rotational velocity. However, we do not know the azimuthal location of this extension in the plane of NGC 891. If this is not along the

---

**Fig. 1.—** Left: Total H\textsubscript{i} image as obtained from the observations described in this paper. The outer gray contour comes from the 60\textquoteleft data, and its level is 0.005 \times 10\textsuperscript{21} cm\textsuperscript{-2}. The black contours come from the 30\textquoteleft data with contour levels of 0.01, 0.02, 0.05, 0.1 (thick line), 0.2, 0.5, 1.0, 2.0, and 5.0 \times 10\textsuperscript{21} cm\textsuperscript{-2}. For comparison of the total H\textsubscript{i} images of NGC 891 published over the years, we show the one from Sancisi & Allen (1979; top right) with a spatial resolution of about 30\textquoteleft and contour levels of 0.5, 1.0, 1.5, 2.4, 4.1, 5.7, 7.3, 8.9, and 10.5 \times 10\textsuperscript{21} cm\textsuperscript{-2} and the total H\textsubscript{i} image as published by Swaters et al. (1997; bottom right). The spatial resolution of the last image is about 20\textquoteleft, and the contour levels are 0.07, 0.17, 0.46, 1.1, 2.3, 4.1, 6.4, and 9.2 \times 10\textsuperscript{21} cm\textsuperscript{-2}. To aid the comparison, two stars labeled "A" and "B" are marked in each figure. [See the electronic edition of the Journal for a color version of this figure.]

---
line of nodes, the decrease in rotational velocity is only apparent and due to projection effects. Note, however, that this extension probably represents a large fraction of the outer disk, as it can be seen in the $p-V$ diagram of Figure 6 on the entire receding side at projected distances from 0' to 11' and on the velocity side closer to systemic.

Above and below the plane of the disk (Fig. 5, bottom panels), the shape of the $p-V$ diagrams changes dramatically. First, the fast-rotating inner component quickly disappears, indicating that it is confined to the inner thin disk. Moreover, the overall shape of the diagram changes from that of a typical differentially rotating disk to that of solid-body rotation. In particular, the two diagrams at $z = \pm 3'$ from the plane clearly show the pattern of a slow solid-body rotator. These features are a first indication of a slow rotation of the gas above the plane with respect to that in the disk.

The $p-V$ diagrams in Figure 3 show the vertical density-velocity structure of NGC 891. The shape of these plots is generally triangular, with the vertex located at the highest rotation velocity (in the plane). This shape was already noted by Sancisi & Allen (1979) in their Figure 7, showing the H I emission on the receding and the approaching sides. At increasing distances upward and downward from the plane, the emission tends to disappear from the high rotation velocity side and to be restricted closer and closer to the systemic velocity ($V_{\text{sys}} = 528$ km s$^{-1}$). This is particularly clear for the emission at very high latitudes. The $p-V$ diagrams at distances from $R = -1'$ to $R = -3'$ (i.e., at 1' and 3' from the center of the galaxy on the northeast side) show emission at low levels up to about 8' (~22 kpc) and concentrated around the systemic velocity of NGC 891. This is the filament visible (Fig. 1) on the northwest side of the galaxy.

The $p-V$ diagrams also show that, if one compares the halo gas in the different quadrants, the kinematics of this gas is quite symmetric up to heights of about 3' (~8 kpc). Beyond this, significant differences exist between the quadrants. This symmetric kinematics in the lower halo could indicate that the gaseous halo in this region is in an equilibrium situation.

A synoptic view of the kinematical structure of the H I gas in the vertical direction (from the disk to the halo region) is shown in Figure 7, where the thickness of the H I (measured as the first moment of the $z$-distribution) is given as a function of position along the major axis and radial velocity. At the high-velocity side (close to rotation) the $z$-distribution is much thinner than at the lower rotational velocity side, as also seen in Figure 3.

3.3. UGC 1807

The present observations also show UGC 1807, a small, gas-rich companion located at a projected distance of about 30' (~80 kpc) from NGC 891 (Fig. 8) (not discussed in previous papers on NGC 891). In the optical, UGC 1807 appears as a LSB galaxy oriented almost face-on. Our H I data show a regular distribution of H I with a symmetric velocity field (Fig. 8). The outer radius of the H I disk is 4 kpc, and the total H I mass corrected for the primary beam attenuation is $4.5 \times 10^8 M_\odot$. We note that at the position of UGC 1807 this correction is quite large, about a factor of 6.

The kinematic parameters of UGC 1807 have been derived with a tilted-ring fit of the velocity field. We found a systemic velocity of 627 km s$^{-1}$, 100 km s$^{-1}$ larger than that of NGC 891, and an inclination of about 15' ± 5'. The rotation curve (Fig. 8) is very regular and shows a slow rising in the inner regions up to a rotation velocity of about 100 km s$^{-1}$ at the last measured point. However, because of the low inclination and its large uncertainty, the amplitude of the rotation curve is very uncertain: it can be as low as 70 km s$^{-1}$ or as high as 140 km s$^{-1}$. Using 100 km s$^{-1}$ and the measured outer radius, we find for UGC 1807 a total mass of $9 \times 10^8 M_\odot$.

3.4. Radio Continuum

Thanks to the broad band and the long integration time of the present observations, we have been able to construct a very deep radio continuum image (Fig. 9), similar in quality to the 21 cm continuum image published by Dahlem et al. (1994). The spatial resolution is $17'' \times 12''$, and the rms noise is 23 mJy beam$^{-1}$. Our data do not contain, however, the information on the polarization of the radio emission. In Figure 10 we show the normalized vertical brightness distribution of the radio continuum halo in the four quadrants of NGC 891. As was found by Dahlem et al. (1994), the vertical brightness distribution of the radio continuum closely follows an exponential profile, with a scale height of 25'' (corresponding to 1.15 kpc) in the northeast, southeast, and southwest quadrants and a bit larger (1.3 kpc) in the northwest quadrant. In the southwest quadrant the radio continuum halo seems to be somewhat more extended. As in the earlier data on NGC 891, there is also a strong north-south asymmetry of the continuum emission in the disk. Dahlem et al. argue, based on the similarity in the distribution of the H$\alpha$ emission and the radio continuum, that both are the result of outflows from the disk driven by star formation. In Figure 10 we also indicate the vertical distribution of the H$\alpha$ emission of the halo, as determined by R. J. Rand & G. H. Heald (2007, private communication).

4. MODELS

Here we investigate the structure and kinematics of the extraplanar H I emission in NGC 891 by constructing model data cubes and comparing these with the observations. We first consider, following Swaters et al. (1997), basic models (§ 4.1) in which the extraplanar emission is produced by a strong warp, a flare, and a corotating thick disk. All these models are easily ruled out by comparison with the data. Then, in § 4.2 we consider more sophisticated models made of two components (disk + halo) with different kinematics.

4.1. Basic Models

We build model data cubes using a modified version of the GIPSY (van der Hulst et al. 1992) program GALMOD. This program assumes axisymmetry and an H I layer made of concentric
rings. For each ring we define the H I column density, the thickness of the layer, and the geometric and kinematic parameters. The H I disk of NGC 891 is not symmetric, being more extended on the southwest (receding) side of the galaxy. In order to avoid the complications arising from this lopsidedness, we construct the models only for the northeast (approaching) side of the galaxy.

We start with a thin-disk model. The H I radial density distribution in the plane of the disk is derived by considering only the northeast side of the galaxy and the region within $|z| < 30''$. The result is plotted in Figure 11. We approximate the observed distribution with an exponential law at large radii and a depression in the inner regions, as described by

$$ \Sigma(R) = \Sigma_0 \left( 1 + \frac{R}{R_s} \right) \exp \left( - \frac{R}{R_s} \right), $$

where $\Sigma_0$ is the central surface density, $\alpha$ is an exponent defining the tapering toward the center, and $R_s$ is a scale radius such
that the peak of the distribution is located at $R = R_c (\alpha - 1)$. The parameters of the fit shown in Figure 11 are $\Sigma_0 = 6.2 \times 10^{-4} M_\odot pc^{-2}$, $\alpha = 7.8$, and $R_c = 1.2$ kpc. In the inner regions of the galaxy ($R \lesssim 3$ kpc) this model fails to reproduce the inner ring that is clearly visible in Figure 6. To reproduce this inner ring as well, we add an extra exponential component to our model. The parameters of this component are $\Sigma_0 = 6.3 M_\odot pc^{-2}$ and $R_c = 1.2$ kpc. The approaching and receding rotation curves in the disk of NGC 891 are shown in Figure 6. In our models, we use the curve derived for the northeast (approaching) side of the galaxy, and we assume a velocity dispersion $\sigma_{\text{gas}} = 8$ km s$^{-1}$.

NGC 891 has a mild warping of the outer disk, as can be seen in the top right panel in Figure 12. In all models, we have included this mild warp by varying the inclination and position angles of the rings beyond $R = 13$ kpc. The warping angles that fit the data are quite small ($1.5^\circ$ in P.A. and $4^\circ$ in inclination). The inclination angle of the inner disk is taken to be $90^\circ$. The vertical distribution has been modeled with an exponential profile with scale height $h_{\text{disk}} = 0.2$ kpc.

Figure 12 (leftmost column) shows the best-fit thin-disk model for NGC 891. The rightmost column shows the data channel maps at full resolution. An important property of the data is that the
Apparent vertical thickness increases from very thin in the $v_{\text{hel}} = 292$ km s$^{-1}$ channel (corresponding to the extreme rotation velocity) to a broad vertical distribution in the bottom channel (close to the systemic velocity, $v_{\text{sys}} = 528$ km s$^{-1}$). This is a major constraint for all our models, as it indicates that there is no halo gas with rotation velocities as high as those of the gas in the disk. Clearly, the thin-disk model only reproduces the top channel at $v_{\text{hel}} = 292$ km s$^{-1}$. The gas visible in this channel is likely to be at the line of nodes, and its thickness is a measure of the intrinsic thickness of the thin disk.

However, because of insufficient resolution (HPBW = 19$''$ = 0.9 kpc in the vertical direction) this channel gives only an upper limit to the thickness of the thin disk (see below).

The second column of Figure 12 shows the effect of a strong warp along the line of sight in addition to the mild warp described above. Such a strong warp model has been proposed by Becquaert & Combes (1997) to explain the extraplanar emission observed in NGC 891 with the VLA (Rupen 1991), in contrast with the model of a thick, lagging layer favored by Swaters et al. (1997). In the present model we have introduced a linear change in the inclination of the outer rings (beyond $R = 13$ kpc) that reaches a tilt of 25$^\circ$ in the outermost ring with respect to the inner parts ($i = 90^\circ$). This model comes close for the top and the bottom channels of Figure 12 but totally fails to reproduce the middle ones. The characteristic feature of any line-of-sight warp model is the “butterfly” opening visible in the middle channels (around $v_{\text{hel}} = 366.2$ km s$^{-1}$; see also Gentile et al. 2003). Such a pattern is totally absent in the present data, and therefore, we can rule out that the extraplanar emission in NGC 891 is produced by a line-of-sight warp.

The middle column of Figure 12 shows the effect of a large flaring of the H I layer. In this model, the thickness of the H I layer in the inner regions is as small as in the thin-disk model ($h_{\text{disk}} \approx 0.2$ kpc), but it increases outward and reaches $h_{\text{disk}} \approx 3$ kpc in the outer rings. Such an unrealistically large value is necessary to produce the emission observed at high latitudes. This model generates some channel maps fairly similar to those observed (e.g., at $v_{\text{hel}} = 366.2$ km s$^{-1}$), but it completely fails to reproduce the thin structure in the top-channel maps. This is because in the model the gas in the outer flare rotates as fast as the gas in the plane. This model can therefore also be ruled out. As already mentioned above, from the thin structure observed at the highest

![Figure 4](image-url)
Fig. 5.—Position-velocity plots parallel to the plane for NGC 891 made from the high-resolution data cube (thin lines and gray scale) and the 60" data (thick line). Contour levels are in steps of 1.5 $\sigma$ for the high-resolution data and 3 $\sigma$ for the low-resolution data. [See the electronic edition of the Journal for a color version of this figure.]
rotational velocities (Fig. 12, top panels), it is possible to derive an upper limit to the thickness of the thin disk and to set an upper limit to its flaring. We find that the inner scale height of the disk is less than $h_{\text{disk}} < 0.3$ kpc, while in its outer regions the disk can flare up to at most $h_{\text{disk}} \sim 0.5$ kpc.

We now consider models made of two components: (1) a thin disk (like that in the leftmost column in Fig. 12) and (2) a thicker layer or halo. For the vertical gas distribution of the latter we use a density profile described by the following empirical function:

$$\zeta(z) = \zeta_0 \frac{\sinh(z/h_{\text{halo}})}{\cosh(z/h_{\text{halo}})^2},$$

where $z$ is the vertical coordinate, $\zeta_0$ is the surface density in the plane, and $h_{\text{halo}}$ is the halo scale height. With this formulation, the vertical density of the thick layer is zero in the plane, then rises, reaching its maximum at $z = 0.88h_{\text{halo}}$, and declines nearly exponentially further out. The half-width at half-maximum (HWHM) of this distribution [defined as the $z$ where $\zeta(z) = \zeta(0.88h_{\text{halo}}/2)$] is at $z = 2h_{\text{halo}}$. Between disk and halo there is a gradual transition. In this way the spatial coexistence between the two components is minimized: the halo takes over when the disk is fading out.

In order to model the gas density in the halo, we have extracted and deprojected the radial distributions at various heights. The left panel of Figure 13 shows two of these deprojected radial distributions (squares) at $z = 2.8$ and 5.6 kpc (average of the northeast and northwest quadrants). The shapes of these distributions change with the height from the plane: as the distance from the plane increases, the radial distribution becomes flatter and less concentrated at the center (cf. Fig. 11). We have fitted the data with the function

$$\rho_{\text{halo}}(R,z) = \Sigma(R) \frac{\zeta(z,h_{\text{halo}}(R))}{\zeta_0},$$

where $\Sigma(R)$ and $\zeta(z,h_{\text{halo}})$ are given by equations (1) and (2) but the scale height $h_{\text{halo}}$ varies with $R$. Figure 13 (right) shows the fitted values (squares) of $h_{\text{halo}}$ as a function of $R$ and a power-law fit (solid line). With this parameterization the scale height of the halo varies from $h_{\text{halo}} = 1.25$ kpc (HWHM = 2.5 kpc) in the central regions to $h_{\text{halo}} \sim 2.5$ kpc (HWHM \sim 5 kpc) in the outer parts. The other parameters of the fit are $\Sigma_0 = 1.4 \times 10^{-1} M_{\odot} \text{pc}^{-2}$, $\alpha = 4.5$, and $R_* = 1.9$ kpc. The final result (lines) is shown in the left panel of Figure 13 (at $z = 2.8$ and 5.6 kpc from the plane).

The fourth column in Figure 12 shows a two-component model in which the halo corotates with the disk. The mass of the halo component is $M_{\text{halo}} = 1.25 \times 10^9 M_{\odot}$, 30% of the total H i mass. Clearly, this model does not correctly reproduce the channel maps at high rotation velocities (top two panels), which appear much thicker in the model than in the data.

### 4.2. Lagging-Halo Models

The failure of the two-component model with a corotating halo to reproduce the channels near the extreme rotation velocity suggests that the gas above the plane is rotating more slowly than that in the plane, i.e., that the halo is lagging in rotation with respect to the disk. Evidence for such a lag was found by Swaters et al. (1997) and is also observed in the ionized gas (Heald et al. 2006a; Kamphuis et al. 2007). Figure 14 shows four models with lagging halos, where the rotation velocity decreases with increasing height above the disk. All these models consist of a thin disk (see Fig. 12) and a halo component with the density distribution described above. Table 4 lists the kinematic parameters used in the lagging-halo models. The first model (leftmost column) is that of a lagging halo with the vertical gradient in rotation velocity independent of radius. The rotation curve in the disk is that shown in Figure 6 (neglecting the inner fast-rotating ring). We have adopted, after a few trials, a constant negative vertical gradient in rotation velocity of $\Delta v_{\text{rot}}/\Delta z = -0.55 \text{ km s}^{-1} \text{ arcsec}^{-1} \sim -12 \text{ km s}^{-1} \text{ kpc}^{-1}$ for the halo component.
It is clear that this simple lagging-halo model reproduces the main features of the data much better than the previous models. The structure in the upper channel maps is as thin as in the data, and it becomes thicker as one approaches the systemic velocity (bottom row). However, this model is still not completely satisfactory. In particular, near the systemic velocity the radial extent of the halo gas is much narrower than in the data. One way to improve the model is to increase the velocity dispersion of the halo gas (Fig. 14, second column). For this model all values of the parameters have been kept the same as in the previous model except for the velocity dispersion of the halo gas, which has been increased to $\sigma_{\text{halo}} = 25 \text{ km s}^{-1}$, and the halo rotation, which has been decreased. The higher velocity dispersion is physically plausible since the gas in the halo is expected to be kinematically "hotter" and to have a more complex motion than the gas in the plane. However, to such an increasing velocity dispersion corresponds a decreasing halo rotation and, therefore, an increasing vertical velocity gradient, to $\Delta v_{\text{rot}}/\Delta z = -0.8 \text{ km s}^{-1} \text{ arcsec}^{-1} \sim -17.4 \text{ km s}^{-1} \text{ kpc}^{-1}$. Figure 14 shows that increasing the velocity dispersion of the halo gas indeed improves the match of the radial extent of the halo $\text{H}i$ in the channel maps close to the systemic velocity (bottom row).

An alternative approach to the increase of the velocity dispersion is to introduce a systematic noncircular motion in addition to the rotation of the halo gas. Such noncircular motions have been found in similar studies of other galaxies. Large-scale inflows toward the galaxy center have been discovered in NGC 2403 ($v_{\text{rad}} \sim -15 \text{ km s}^{-1}$; Fraternali et al. 2001) and in NGC 4559 (Barbieri et al. 2005). The third column of Figure 14...
shows the effect of an overall radial motion of the halo of \( |v_{rad}| \lesssim 25 \text{ km s}^{-1} \). This is of about the same amplitude as found in NGC 2403 (although in an edge-on galaxy one cannot discriminate between in- and outflow). The models also show that the effects of a higher velocity dispersion or radial motions in the halo are very similar. It is therefore not possible to discriminate between an in/outflow and a higher velocity dispersion of the halo gas.

All the models described above do reproduce most of the features present in the data, but do not fully account for the shape of the middle-channel maps of NGC 891. Let us focus in particular on the channel map at \( v_{hel} = 366.2 \text{ km s}^{-1} \). The shape in the data channel map is roughly triangular, while in the models it is more boxy. Clearly, in the model channels near \( v_{hel} = 366.2 \text{ km s}^{-1} \), there is too much halo emission near the center. In order to obtain the triangular shape, we consider two possibilities. The first is that the inner regions of the halo are depleted of gas (much more than shown in Fig. 11). This obviously would decrease the amount of gas near the center in the models. The second possibility is that the gradient in rotation velocity in the inner parts of the galaxy is larger than in the outer parts. First we consider the possibility of a stronger central gas depletion in the halo. Since the gas density in the halo was derived from the data (without any assumptions about the kinematics), and modeled accordingly, we do not expect the \( \text{H}_\text{i} \) density used to be significantly different from the actual one. The main source of errors is the deprojection of the radial profiles. However, this is not expected to have a strong effect beyond \( R > 3 \text{ kpc} \), while in order to reproduce the channel map at \( v_{hel} = 366.2 \text{ km s}^{-1} \), the gas density should be significantly lower than the one used here for radii as large as \( R \sim 8 \text{ kpc} \). Therefore, it seems unlikely that a central depletion is the explanation.

Consider instead the second possibility. The fourth column in Figure 14 shows a model (named “shallow rise”) in which the vertical gradient in the rotation velocity varies with \( R \). In the inner regions, the gradient is quite large \( \Delta v_{rot}/\Delta z = -43 \text{ km s}^{-1} \text{ kpc}^{-1} \) at \( R = 0 \), and it decreases linearly with \( R \) \( \Delta(v_{rot}/\Delta z)/(\Delta R \sim 2.5 \text{ km s}^{-1} \text{ kpc}^{-2}) \) until it reaches a value of \( \Delta v_{rot}/\Delta z = -14 \text{ km s}^{-1} \text{ kpc}^{-1} \) and remains constant further out. The shape of the rotation curve of the halo changes with distance from the plane: its inner rising part becomes shallower and shallower. This behavior is illustrated in Figure 15. Clearly, this model gives a better representation of the channel at \( v_{hel} = 366.2 \text{ km s}^{-1} \) while keeping the other channel maps almost unchanged (note that this shallow-rise model also has a high \( \sigma \) for the halo gas and an inflow similar to the previous two models). The rotation curves for the halo gas at various distances from the plane, derived directly from the observations, will be presented and discussed by F. Fraternali (2007, in preparation).

We further compare the models by inspecting the position-velocity cuts perpendicular to the major axis of the galaxy. Figure 16 shows two sets of such cuts taken on the northeast side of the galaxy at a distance of \( 1' \) (2.8 kpc, bottom) and \( 2.7' \) (7.5 kpc, top) from the center. The emission shows a characteristic triangular shape. The thin disk is visible at all velocities between systemic \( (v_{hel} = 528 \text{ km s}^{-1}) \) and the maximum rotation \( (v_{hel} \sim 290 \text{ km s}^{-1}) \), whereas the halo appears to have its maximal extent near the systemic velocity. It is clear that the shallow-rise model best reproduces the triangular shape, as well as the difference between the \( 1' \) and \( 2.7' \) plots. The white squares in the data plots show the rotational velocities adopted for the shallow-rise model.

The comparison of the various models leads to the conclusions that the thin disk of NGC 891 is surrounded by an extended gaseous halo which is rotating more slowly than the disk and
contains almost 30% of the neutral gas of the galaxy. The kinematics of the gas in the halo can be best explained by assuming a vertical gradient in the rotation velocity. Moreover, this gradient is stronger in the inner regions ($\Delta v_{\text{rot}}/\Delta z \simeq -43$ km s$^{-1}$ kpc$^{-1}$) than at larger radii ($\Delta v_{\text{rot}}/\Delta z \simeq -14$ km s$^{-1}$ kpc$^{-1}$). Finally, the velocity dispersion of the halo gas is higher than that of the gas in the disk ($\sigma_{\text{halo}} \simeq 20-25$ km s$^{-1}$ vs. $\sigma_{\text{disk}} \simeq 8$ km s$^{-1}$), and/or there are significant radial motions in the halo gas ($|v_{\text{rad}}| \lesssim 25$ km s$^{-1}$).

5. DISCUSSION

In the previous section we studied with three-dimensional models the extended extraplanar H$_i$ emission of NGC 891 and concluded that this galaxy has a massive halo of neutral gas rotating more slowly than the disk. Here we discuss the properties of this H$_i$ halo, its possible origins, and the comparison with data at different wavelengths.

5.1. The Structure of the H$_i$ Halo

The H$_i$ halo of NGC 891 is the most extended and massive of those found to date in a spiral galaxy (Fraternali et al. 2007b). The H$_i$ mass above $z = 1$ kpc is about 30% of the total H$_i$ mass. The distribution of gas in the halo appears fairly symmetric and regular in the four quadrants of the galaxy up to about 8 kpc from the plane (Figs. 1 and 2). In three quadrants, the H$_i$ extends up to about 14 kpc, whereas the northwest quadrant is dominated by an extended filament reaching up to 8$'$ (\(~22$ kpc). Radially, the halo extends to the end of the disk on the northeast side but

---

**Fig. 12.**—Comparison between five representative channel maps for NGC 891 (rightmost column) and models. From left to right the models are thin disk, strong warp along the line of sight, disk flare, and disk + corotating halo. Heliocentric velocities (km s$^{-1}$) are shown in the top left corners of the data channel maps ($v_{\text{sys}} = 528$ km s$^{-1}$).
stops earlier on the southwest side, where the disk is more extended. This may be an indication that the halo is closely connected to the inner disk of NGC 891.

Also, the kinematics of the halo is symmetric and regular in the four quadrants up to a height of about 8 kpc (Fig. 5). The gradient in the rotation velocity can be measured up to about 5 kpc. Above that the rotation velocity continues to decrease further, but the gas density is too low to derive reliable rotation velocities (Fraternali et al. 2005). The gas in the halo may have radial motions and/or higher velocity dispersion than the disk gas, as the above model analysis indicates (§4.2). Vertical motions may also be present (as in NGC 2403; Fraternali et al. 2001), but because of the inclination of the galaxy they cannot be observed.

The halo of NGC 891 shows individual features (streams and compact clouds) somewhat “separated” in either location or kinematics from its main bulk. The most prominent feature is the extended filament in the northwest quadrant (see Figs. 1 and 3). This feature has a mass of more than $1.6 \times 10^7 M_{\odot}$, and it extends out to a projected radius of about 10 kpc from the center of the galaxy and vertically up to 22 kpc (Figs. 3 and 4). The full length of the filament is about 30 kpc, its velocity width is $\Delta v \lesssim 100$ km s$^{-1}$, and its mean velocity is close to systemic for $z \gtrsim 10$ kpc.

A key question is whether the H i halo of NGC 891 is a diffuse medium (filling factor $\sim 1$) or is entirely made of discrete compact clouds. A first inspection of the data cube seems to indicate that most of the gas belongs to a smooth, coherent, differentially rotating structure. This picture of a “diffuse medium” may, however, be erroneous and be produced, at least to some extent, by projection effects along the line of sight. Only clouds with anomalous velocities or located at large distances from the plane would stand out clearly (such as those shown in Fig. 4). These clouds, together with the filament in the northwest quadrant, may be evidence that the halo of NGC 891 is indeed made, at least partly, of individual gas complexes. These complexes would be similar to those observed in non-edge-on galaxies like NGC 2403 and NGC 6946, where projection effects are less important (Fraternali et al. 2002; Boomsma et al. 2005a; Boomsma 2007). Moreover, they would have similar properties to the HVCs and IVCs of the Milky Way (Wakker & van Woerden 1997) and the clouds seen near M31 (Westmeier et al. 2005).

A structure like the long northwest filament would probably appear as a “Complex A” or “Complex C” of the HVCs to an observer inside NGC 891.

5.2. Origin of the H i Halo

What is the origin of the H i halo of NGC 891? We discuss here two possibilities: a galactic fountain and accretion from outside. The main observational facts to be accounted for are that (1) the halo is very extended and massive (about 30% of the total H i mass); (2) the halo kinematics is dominated by differential rotation, and the rotation velocity decreases with height from the plane; (3) a high velocity dispersion or noncircular motion (maybe inflow?) is also present; (4) the halo is structured in clouds and filaments, some of which are at very anomalous (counterrotating) velocities; and (5) as the distance from the plane increases, the radial distribution of the gas in the halo tends to become flatter and less concentrated at the center than in the disk, and on the southern side, the halo is radially less extended than the disk.

5.2.1. Fountain

There is considerable evidence from H$\alpha$ radio continuum and X-ray data pointing at a galactic fountain mechanism playing a major role in forming the gaseous halo of NGC 891. The H$\alpha$ image of NGC 891 (Dettmar 1990; Rand et al. 1990) indicates that the star formation rate in the disk, especially on its northern side, is very high. There is strong radio continuum emission (thermal and nonthermal) in the disk and also (nonthermal) in the halo, extending up to $\sim 10$ kpc from the plane (see Fig. 9). This extent is close to that of the H i halo and indicates the presence of magnetic fields and relativistic electrons in correspondence with the H i gas. Also, there is a clear correlation between this radio emission and the H$\alpha$ halo (Dettmar 1990; Rand et al. 1990; Dahlem et al. 1994). In particular, the northern side of the galaxy is much brighter in both components, and in the northwest quadrant the radio halo has a larger scale height (Fig. 10). A corresponding north-south asymmetry is also seen in the H i halo. Figure 7, which shows the thickness of the H i layer as a function of position and velocity, indicates that in the inner regions of the disk (corresponding to small $R$ and velocities furthest away from systemic), the H i disk is thicker on the northern (i.e., approaching) than on the southern side. The northern side of the disk is where star formation and consequently the fountain are strongest.

The ionized gas in the halo of NGC 891 has a smooth component (diffuse ionized gas), but it also shows filamentary structures (Howk & Savage 2000). Collimated H$\alpha$ filaments are
seen reaching up to more than 2 kpc from the plane (Rossa et al. 2004). Moreover, the radio emission is strongly polarized. Both these features suggest the presence of a uniform magnetic field in the halo, indicating that the outflowing gas has also torn the $B$-field out of the disk (Dahlem et al. 1994). Interestingly, the long H i filament found in our data is also similarly oriented. However, in the Hα images there is no trace of an ionized counterpart of the H i filament to the detection limit.

Hot coronal gas was first revealed in NGC 891 by ROSAT (Bregman & Pildis 1994). Recently, Chandra and XMM-Newton data have confirmed this detection and have shown the presence of filamentary substructures in the halo component extending up to about 5–6 kpc from the plane (Strickland et al. 2004), while the soft halo component seems to be concentrated at the inner disk (Tüllmann et al. 2006b). These authors were able to show for a sample of galaxies, including NGC 891, that the amount of hot gas is proportional to the mechanical feedback from supernovae, concluding that this hot gas is almost certainly produced by a fountain. The X-ray emission also correlates fairly well with the Hα emission (Rossa et al. 2004), and the X-ray spectrum of the halo emission in the range 0.3–2 keV is fitted by a plasma with a temperature of 0.23 keV ($3.7 \times 10^6$ K).

Besides the H i there are also in NGC 891 other “cold” extraplanar components such as dust and CO. The dust shows up as absorption features against the starlight up to heights of about

---

**Fig. 14.—** Comparison between five representative channel maps for NGC 891 (rightmost column) and models. All the models have a two-component (disk + halo) structure, with the halo lagging in rotation velocity with respect to the disk. From left to right they are: lagging halo with constant gradient, lagging halo with high velocity dispersion, lagging halo with a radial inflow motion, and lagging halo with velocity gradient increasing in the inner parts. Heliocentric velocities (km s$^{-1}$) are shown in the top left corners of the data channel maps ($v_{sys} = 528$ km s$^{-1}$).
2 kpc (Howk & Savage 1997, 2000). Such features have masses of about $10^7 M_\odot$ (using the galactic dust-to-gas ratio). This cold medium does not seem to correlate, on small spatial scales, with the warm medium observed in Hα (Howk & Savage 2000; Rossa et al. 2004); thus, the two phases appear to be physically distinct. CO emission is also observed up to about 2 kpc from the plane of NGC 891 (García-Burillo et al. 1992; Sofue & Nakai 1993). This extraplanar component of molecular gas comprises about 35% of the total amount of molecular gas.

All this evidence suggests that a classical galactic fountain (ionized outflow, cooling, and cold inflow) is active in NGC 891 and is responsible for much of the gaseous components, at least in the lower halo ($z \leq 5$ kpc). These components have a total mass on the order of a few $10^9 M_\odot$. Among them, the H$i$ halo is the most massive and the most extended, reaching a distance from the plane of more than 20 kpc. This latter may be the result of an observational bias or an indication that a different mechanism, perhaps accretion from outside (see below), is responsible for the formation of the upper layers.

Galactic fountain models can easily explain the distribution of the H$i$ in the halo of NGC 891, with the exception of the extended filament (see below). Indeed, only a few percent of the energy from supernovae would be sufficient (Fraternali & Binney 2006). However, such models fail to reproduce the kinematics of the halo gas (both ionized and H$i$). The ionized component was initially studied using long-slit spectroscopy (Rand 1997) and more recently using the WIYN integral field unit (Heald et al. 2006a) and TAURUS spectroscopy (Kamphuis et al. 2007). The gradient in rotation velocity derived for the ionized gas in the latter study is in good agreement with that observed in H$i$, about $-15$ km s$^{-1}$ kpc$^{-1}$ for 1 kpc $< z < 5$ kpc. This result indicates that the H$i$ and H$\alpha$ phases are part, at least in the lower halo, of the same phenomenon, and therefore probably also have the same origin. A similar coupling between ionized and neutral halo gas has also been found in the spiral galaxy NGC 2403 (Fraternali et al. 2004). This observed gradient in rotation velocity with $z$ is significantly higher than predicted by the fountain models (Fraternali & Binney 2006; Heald et al. 2006a). The only way to reconcile these models with the data is to find a mechanism that would make the fountain gas lose part of its angular momentum. One possibility is that it is braked by the hot halo. However, in this case, the angular momentum transfer to the hot halo would speed it up very quickly (Fraternali et al. 2007a). A second, more promising possibility is that the fountain gas interacts with low angular momentum material accreted from the IGM (F. Fraternali & J. J. Binney 2007, in preparation).

5.2.2. External Origin

It is clear from the foregoing discussion that a “fountain” origin for most of the H$i$ in the halo of NGC 891 is very likely. But a continuous supply of low angular momentum material from outside may also be needed to account for the observed H$i$ kinematics. The amount of accreted gas, however, can be small, perhaps not more than 10% of the gas present in the halo (F. Fraternali & J. J. Binney 2007, in preparation).

Is there any direct observational evidence of such gas infall in NGC 891? An obvious candidate for accretion is the filament in the northwest quadrant extending up to 22 kpc from the plane. As mentioned above, this filament has a projected velocity close to systemic. This may indicate either of two possibilities: (1) the filament belongs to the inner parts of the halo and has a very small $z$-component of the angular momentum, or (2) it is located in the far outer parts of the halo. For the filament to be produced by a galactic fountain, one would require very high kick velocities and a very high initial kinetic energy. Using the galactic fountain model of Fraternali & Binney (2006), we estimate that the required kick velocities to send material up to $z = 15$ kpc range from 240 km s$^{-1}$ for a starting radius of 10 kpc to 425 km s$^{-1}$ for a starting radius of $R = 2$ kpc. For a mass of the filament of $1.6 \times 10^7 M_\odot$, the kinetic energies would be $1 - 3 \times 10^{55}$ ergs. Therefore, to produce such a filament in one single event, hundreds of thousands of supernovae would be required. This seems quite unlikely. If instead the gas complex had an external origin, its filamentary structure and its kinematics might be easier to explain: a cloud falling onto NGC 891 would be stretched out and might speed up to full rotation as it gets close to the disk.

An external origin for the filament may be cold accretion from the IGM. Or it may be through a condensation of the hot coronal gas, possibly triggered by the galactic fountain. Alternatively, the filament could be the result of the merging of a companion with NGC 891. The stellar part of the companion could be elsewhere or too faint to be seen, and the filament would be the only prominent remnant of the process. In this respect we note that deep H$i$ observations are a powerful tool to look for this kind of event and could be used to detect merging at much larger distances than with optical data.

Finally, we note that the filament roughly points at the projected position of the companion UGC 1807 (Fig. 8), and one may wonder whether it could have originated from a close encounter of UGC 1807 with NGC 891. The filament would have to be either gas pulled up from the outer disk of NGC 891 or gas stripped from the companion. This is not impossible, in spite of the present large separation of UGC 1807 from NGC 891 and from NGC 2403 (Fraternali et al. 2004). This observed gradient in rotation velocity with $z$ is considered to be a signature of the galactic fountain model of Fraternali & Binney (2006), as the ionized gas in the latter study is in good agreement with that observed in H$i$, about $-15$ km s$^{-1}$ kpc$^{-1}$ for 1 kpc $< z < 5$ kpc. This result indicates that the H$i$ and H$\alpha$ phases are part, at least in the lower halo, of the same phenomenon, and therefore probably also have the same origin. A similar coupling between ionized and neutral halo gas has also been found in the spiral galaxy NGC 2403 (Fraternali et al. 2004). This observed gradient in rotation velocity with $z$ is significantly higher than predicted by the fountain models (Fraternali & Binney 2006; Heald et al. 2006a). The only way to reconcile these models with the data is to find a mechanism that would make the fountain gas lose part of its angular momentum. One possibility is that it is braked by the hot halo. However, in this case, the angular momentum transfer to the hot halo would speed it up very quickly (Fraternali et al. 2007a). A second, more promising possibility is that the fountain gas interacts with low angular momentum material accreted from the IGM (F. Fraternali & J. J. Binney 2007, in preparation).

### Table 4

| Model                | $\Delta V_{rot}/\Delta z$ (km s$^{-1}$ kpc$^{-1}$) | $\sigma_{gas}$ (km s$^{-1}$) | $v_{out}$ (km s$^{-1}$) |
|----------------------|-----------------------------------------------|--------------------------------|--------------------------|
| Lagging halo         | $-12.0$                                       | $8$                           | $0$                      |
| High $\sigma$        | $-17.4$                                       | $25$                          | $0$                      |
| Inflow               | $13.0$                                        | $8$                           | $-25$                    |
| Shallow rise         | $-43.0$ to $-14.0$                            | $20$                          | $-15$                    |

![Rotation curve as a function of $z$ used in the modeling. In the inner region they become shallower for increasing $z$-distances from the plane (1.5, 3.0, and 4.5 kpc).](plot.png)
its symmetrical structure and kinematics, which would seem to exclude recent tidal encounters. The projected distance of about 80 kpc could have been covered by a companion with a velocity of \(100 \pm 200 \text{ km s}^{-1}\) in \(8 \times 4 \times 10^8\) yr. This is sufficiently longer than the dynamical timescales in the outer parts of the companion (2 \(\times 10^8\) from 100 km s\(^{-1}\) rotation at 4 kpc radius) to account for the absence of any sign of disturbances. On the other hand, the filament, presumably located in the outer parts of NGC 891, would have survived long enough to be observed now. In this connection it is interesting to draw attention to another puzzling, long-known structure revealed by the HI observations of NGC 891: the extended southern tail. This is difficult to maintain for a long time against the effect of differential rotation (Baldwin et al. 1980), and the possibility of a recent origin (less than \(1 \times 10^9\) yr) would therefore be quite attractive. It is therefore interesting to ask whether a tidal encounter with UGC 1807, as considered here for the origin of the filament, could also be responsible for the north-south HI lopsidedness of NGC 891. Note that the mass of the companion (\(\sim10\%\) of that of NGC 891) is not negligibly small.

Other indications of accretion are the counterrotating clouds shown in Figure 4. These clouds cannot be produced by a galactic fountain, as they have an orientation of angular momentum opposite to the gas in the disk. They are almost certainly located in the outer halo (one is observed at a projected distance of 28 kpc); otherwise, the drag by the corotating HI would have quickly inverted their motion. Note that one of these cloud complexes is spatially (and kinematically) very close to the filament. The total HI mass present in those accreting clouds (filament included) is \(\approx 0.1 \times 10^7\) \(M_\odot\). Considering a typical infalling time on the order of \(10^8\) yr, this would correspond to an accretion rate of \(\approx 0.1\) \(M_\odot\) yr\(^{-1}\). This latter should be considered as a lower limit to the total accretion rate, as most of the accreting material may be impossible to detect after it has interacted with the fountain halo.

6. SUMMARY OF RESULTS

The deep HI observations of NGC 891 reported here have shown the following:
1. The HI halo is considerably more extended than shown in previous observations. It is detected out to a vertical distance of about 22 kpc from the galactic plane and contains \(1.2 \times 10^9\) \(M_\odot\), amounting to about 30\% of the total HI. The halo is not smooth. It shows structures on various scales, and there are, in particular, also HI clouds with very anomalous (counterrotating) velocities. These have masses of about \(1 \times 10^6\) \(M_\odot\). Furthermore, there is a striking long filament extending (in projection) up to more than 20 kpc from the disk and containing more than \(1.6 \times 10^7\) \(M_\odot\).
2. The HI halo has overall regular differential rotation, but it rotates more slowly than the disk (as already found by Swaters et al. 1997). The vertical gradient of the rotational velocity is about \(-15\) km s\(^{-1}\) kpc\(^{-1}\). The shape of the halo rotation curves does not remain constant with distance from the plane, but its rising part becomes shallower and shallower with height. Random motions in the halo or systematic deviations from circular motion (in- or outflows) may also be present.
3. A significant fraction of the HI halo must come from a galactic fountain, as the high star formation rate in the disk strongly suggests. The radio continuum, the H\(\alpha\), and the X-ray data are all corroborating evidence. However, the kinematics of the halo suggests the need of an interaction between the fountain gas and low angular momentum material. Such material may be supplied by gas accretion from the surrounding IGM. The long HI filament and the counterrotating clouds may be direct evidence of such accretion.
