Photon-photon scattering in vacuum is extremely weak. However, strong effective interactions between single photons can be realized by employing strong light-matter coupling. These interactions are a fundamental building block for quantum optics, bringing many-body physics to the photonic world and providing important resources for quantum photonic devices and for optical metrology. In this Colloquium, we review the physics of strongly-interacting photons in one-dimensional systems with no optical confinement along the propagation direction. We focus on two recently-demonstrated experimental realizations: superconducting qubits coupled to open transmission lines, and interacting Rydberg atoms in a cold gas. Advancements in the theoretical understanding of these systems are presented in complementary formalisms and compared to experimental results. The experimental achievements are summarized alongside a description of the quantum optical effects and quantum devices emerging from them.

I. INTRODUCTION

Photons, the carriers of the electromagnetic force, are elementary particles with no charge and zero rest mass. Photon-photon scattering in vacuum is extremely weak (Iacopini and Zavattini, 1979; Karplus and Neuman, 1951; Schwinger, 1951) and has, in fact, never been experimentally observed at optical or lower frequencies (Zavattini et al., 2012). This makes photons excellent long-distance carriers of classical and quantum information. However, this seclusion of photons poses substantial challenges for efficiently employing them for information processing. In classical communication networks, optical signals are often converted to electrical signals, which can then be manipulated using solid-state devices. However, existing conversion methods are inefficient at the few-photon level and are ill-suited for quantum information processing. This has motivated scientists in a number of fields, such as nonlinear quantum optics and cavity quantum electrodynamics, to study effective photon-photon interactions (Gibbs, 1985) with the ultimate goal of strong and controllable coupling between single photons. Interactions at the single-photon level are essential for a wide variety of quantum-optical applications. For instance, they form the basis for all-optical quantum gates (Imamoglu et al., 1997) and enable metrology beyond the standard quantum limit (Napolitano et al., 2011). They are also important from the fundamental physics viewpoint, endowing photonic systems with matter-like properties and realizing strong correlations...
and quantum many-body behavior in light \cite{Carusotto2013,Chang2008}.

Cavity quantum electrodynamics (QED) is a paradigmatic discipline \cite{Haroche2013,Miller2005,Walther2000} exhibiting effective photon-photon interactions in the quantum regime \cite{Birnbaum2005,Schuster2008}. In cavity QED, atoms are placed inside a high-finesse electromagnetic resonator, in which the radiation spectrum is discrete. Bouncing between the resonator mirrors, a single photon interacts with the atoms effectively many times, significantly enhancing the atom-photon coupling. This in turn can generate strong correlations between the photons. Cavity QED experiments with free atoms have been carried out with alkali metals in optical cavities \cite{Birnbaum2005,Dayan2008,Mabuchi2002,Scuster2008,Thompson2012} and with Rydberg atoms in microwave cavities \cite{Deleglise2005,Guerlin2007,Nogues2009,Raimond2001}. Cavity QED experiments have also been conducted on a variety of solid-state systems, including quantum dots (QDs) in photonic crystals \cite{Badolato2005,Carter2013,Englund2007,Fushman2008,Hennessy2007,Yoshie2004} and superconducting microwave circuits. In the latter, known as circuit QED, superconducting qubits acting as artificial atoms are coupled to microwave photons in Fabry-Pérot cavities made of coplanar waveguides as shown in Fig. 1(a). Both the fields of cavity and circuit QED have been very successful, providing both significant fundamental results and important advances in quantum information science. Nevertheless, the cavities used to enhance the coupling in these systems also present several disadvantages, for instance, the narrow bandwidth of the emitted photons and the problem of stochastic release of photons by the cavity \cite{Hoi2012}. A related challenge is the coupling of photons into and out of the cavities with high efficiency, as is required to link large numbers of nodes in quantum networks \cite{Aoki2009}.

Because of these limitations, much recent work has focused on cavity-free systems. The coupling strength in these system can be quantified by the extinction of a propagating photon by a single emitter (1 − T), where T is the transmission coefficient. Although the nomenclature is still settling, a reasonable definition of strong coupling in these open systems is that 1 − T > 50%, which implies that the emission rate from the atom into the desired mode is larger than the decoherence rate associated with all other process, including emission into other modes. \cite{vanEnk2001, Zumofen2008} showed theoretically that a single atom can fully block (1 − T = 100%) photons in open space, if their spatial and temporal modes match the atomic radiation pattern, while a tightly focused beam is limited to 1 − T < 85%. In both cases, photons are transversely focused to an area. A comparable with the scattering cross-section of the atom σa, and their electric field becomes large enough to excite the atom with near unity probability. The highest extinction by a single emitter experimentally achieved in three-dimensional (3D) open space is 1 − T = 30% \cite{Maser2016}.

A major barrier to higher extinction in open space is the spatial-mode mismatch between the incident and scattered waves. This problem has recently been solved in two complementary ways, leading to strong coupling and photon-photon interactions in cavity-free one-dimensional (1D) systems:

(i) **Superconducting qubits in open transmission lines**, which are related to circuit QED systems, as illustrated in Fig. 1(b). These systems enhance the coupling in two ways, both inherited from circuit QED. Most importantly, superconductors can confine the microwave fields to deeply subwavelength sizes in the transverse dimensions. This produces a mode volume, in units of cubic wavelengths, that is orders of magnitude smaller than that of 3D cavities or free fields. In addition, transition dipoles of superconducting qubits are much larger than those of real atoms. These effects together allow for the observation of strong coupling \cite{Astafiev2010}, extinctions of 1 − T > 99% \cite{Hoi2011}, and strong photon-photon correlations \cite{Hoi2012}.

(ii) **Rydberg atoms excited by focused optical beams in a dense atomic gas**. In these systems, strong coupling is achieved by greatly enhancing the size of the effective scatterer, thereby achieving mode matching to collimated light beams. The dipolar interaction between Rydb erg atoms prevents the excitation of more than one Rydberg atom inside the volume of a so-called **blockade** sphere. With only zero or one excitation, each blockade sphere thus acts as a “superatom” \cite{Vuletic2006}. The weak coupling of photons to each individual atom can sum up in a dense gas to a strong effective coupling with the superatoms, leading to extinction of 1 − T ≥ 95% \cite{Baur2014}. As long as the blockade sphere is wider than the beam waist, as illustrated in Fig. 1(c), the evolution is limited to the longitudinal 1D continuum. Photon-photon interactions were observed in this system, with

\[ T = \frac{1}{1 + \frac{\sigma_a}{\sigma_\text{ext}}}. \]
photons either blocking \cite{Peyronel:2012} or spatially attracting \cite{Firstenberg:2013} each other.

These cavity-free systems feature intrinsically nonequilibrium, quantum many-body dynamics. The input field is driven by either a laser or microwave generator, imposing a nonequilibrium boundary condition on the propagating photons in 1D. Therefore, the study of photon-photon correlation mediated by local light-matter coupling in 1D calls for advanced quantum field theories in the strongly-interacting and nonequilibrium regimes. Traditionally, photon transport in this type of system is studied by employing a master equation that assumes a weak coherent state as input and usually involves approximations such as linearization of operator equations (see Sec. II.B for details) and the Markovian approximation \cite{Agarwal:2013}. Here, we review the recent progress in developing new analytical and numerical techniques to study collective scattering of multiple photons from two-, three-, or multi-level emitters in a 1D continuum.

This Colloquium presents an overview of this research, emphasizing the systems discussed above. Other 1D systems with artificial atoms, which are outside the scope of this paper, include QDs coupled to surface plasmons of a metallic nanowire \cite{Akimov:2007b, Akselrod:2014, Versteegh:2014, Javadi:2015, Laucht:2012, Lodahl:2013}, and QDs or nanocrystals coupled to semiconductor or diamond nanowires \cite{Babinec:2010, Claudon:2010, Reithmaier:2008}. In addition, strong coupling to single emitters in 1D can also be achieved in an ion trap \cite{Meir:2014}, with cold atoms trapped inside \cite{Baas:2009} or near \cite{Vetsch:2010} an optical fiber, or with single molecules doped in an organic crystal inside a glass capillary \cite{Faez:2014}.

In Sec. II we summarize the theoretical approaches and experimental results for systems with single emitters, along with a systematic description of various phenomena and their application to quantum information processing. Theories and experiments with multiple emitters are presented in Sec. III in the strong-coupling regime, and in Sec. IV in the weak-coupling regime in systems of interacting Rydberg atoms. We conclude with a short discussion on current research challenges in Sec. V.

II. SINGLE EMITTER

A model configuration of a two-level emitter (2LE) side coupled to photons in a waveguide is shown in Fig. 2(a). This is a common model for superconducting qubits coupled to a transmission line \cite{Astafiev:2010a, Hoi:2010} and for QDs coupled to surface plasmons \cite{Akimov:2007b, Wallraff:2004}. The model in Fig. 2(b) has the 2LE directly coupled to the photons in the waveguide. This model is popular for atomic cavity QED experiments \cite{Birnbaum:2005} and is also often used in experiments with line-defect photonic crystals \cite{Faraon:2007, Park:2008}. The transmission and reflection of photons in the side-coupled configuration can be mapped to those in the directly coupled configuration \cite{Shen:2009}

Our model system also connects to a number of problems important in condensed matter physics, for instance, the general problem of quantum tunnel in open \cite{Costi:1983} systems \cite{Caldeira:1983}. There are also exact analogies to various other nonequilibrium quantum impurity models, including the Kondo model \cite{French:2009, Leggett:1987}, which have been renewed importance in describing decoherence in various implementations of quantum bits. In the systems of interest in this colloquium, the photons in the 1D continuum play the role of the bosonic bath in the condensed-matter models. There are also exact analogies to various other nonequilibrium quantum impurity models, including the Kondo model \cite{French:2009, Leggett:1987}, which have been renewed importance in describing decoherence in various implementations of quantum bits.
in superconducting systems. The interaction of the propagating photons with the 2LE is governed by $\hat{H}_1$, which is written in the rotating-wave approximation. This is valid for typical light-matter coupling strengths available in recent experiments. Here $a_k$ ($a_k^\dagger$) is the photon annihilation (creation) operator, and the coupling strength of a photon of wavevector $k$ with the emitter is $V_k$.

The energy-momentum dispersion ($\omega_k$ versus $k$) of photons in various 1D waveguides is generally nonlinear and depends on the properties of the waveguide. However, it is convenient to assume linear dispersion to describe the first two theoretical approaches discussed here. We can linearize the dispersion near some arbitrary frequency $\omega_0$ with the corresponding wavevector $\pm k_0$ as shown in Fig. 3. The approximate linearized dispersion of $\omega_k$ around $k_0$ (right-moving photons) and $-k_0$ (left-moving photons) reads

$$\int_{k\approx k_0} \omega_k a_k^\dagger a_k \simeq \int_{k\approx k_0} (\omega_0 + v_g (k - k_0)) a_{R,k}^\dagger a_{R,k},$$

$$\int_{k\approx -k_0} \omega_k a_k^\dagger a_k \simeq \int_{k\approx -k_0} (\omega_0 - v_g (k + k_0)) a_{L,k}^\dagger a_{L,k},$$

where $a_{R,k}^\dagger$ ($a_{L,k}^\dagger$) creates a right-(left-)moving photon and $v_g$ is the group velocity of photons at $\omega_0$. Thus we divide the propagating photons into two oppositely moving modes (channels). Next, we extend the limits of the integration over $k$ to ($-\infty, \infty$) for the left and right-moving photons, as we are only interested in photons with a narrow bandwidth in the vicinity of $\omega_0$, and we make a change of variables $k \mp k_0 \to k$ for the right- and left-moving photons.

The total excitation operator $N_E = \int dk \ [a_{R,k}^\dagger a_{R,k} + a_{L,k}^\dagger a_{L,k}] + |e\rangle\langle e|$ commutes with the linearized Hamiltonian $\hat{H}$. Subtracting the term $\hbar \omega_0 N_E$ from the linearized $\hat{H}$ gives the final Hamiltonian $\hat{H} = \hat{H}_0 + \hat{H}_1$, where

$$\frac{\hat{H}_0}{\hbar} = \int_{-\infty}^{\infty} dk \ v_g k (a_{R,k}^\dagger a_{R,k} - a_{L,k}^\dagger a_{L,k}) + (\omega_e - i\gamma)|e\rangle\langle e|,$$

$$\frac{\hat{H}_1}{\hbar} = \int_{-\infty}^{\infty} dk [\mathcal{V}_k (a_{R,k}^\dagger + a_{L,k}^\dagger)] |g\rangle\langle e| + h.c.,$$

with $\omega_e = \tilde{\omega}_e - \omega_0$.

Several interrelated theoretical techniques have been employed in recent years for investigating correlated photon dynamics in a 1D continuum. We can divide them into five different groups: (a) multiparticle scattering theory in a continuum (Roy 2010a, Shen and Fan 2007a,b, Yudson and Reinke 2008, Zheng et al. 2010), (b) the input-output formalism of quantum optics (Fan et al. 2010, Koshino and Nakamura 2012, Peropadre et al. 2013), (c) an approach based on the Lippmann-Schwinger equation (Roy 2011a, Zheng and Baranger 2013), (d) a method based on the Lehmann-Symanzik-Zimmermann reduction for the multiphoton scattering process (Shi and Sun 2009), and (e) the time-dependent, wave-packet evolution approach (Longo et al. 2010). Scattering theory is a well-known framework to study scattering of waves and particles within the Schrödinger picture of quantum mechanics, and it has been extensively applied in different branches of physics. The input-output formalism was mainly developed for understanding light-matter interaction, and it is based on the Heisenberg picture. In what follows, we carefully discuss these two techniques and the connection between them. We briefly mention the applications of the other approaches later on.

### A. Scattering theory

In scattering theory, the scattering matrix $S$ expresses how an incoming state of monochromatic, free photons evolves via a local interaction with atoms into a superposition of outgoing monochromatic photons. The $S$-matrix for scattering of an $N$-photon state is defined by (Newton 1982, Taylor 2006)

$$S^{(N)}_{p;k} = \langle p | S | k \rangle,$$

where $|k\rangle$ and $|p\rangle$ are incoming and outgoing photonic states respectively. Here, the vectors $k$ and $p$ denote the incoming and outgoing momenta of the $N$ photons. These incoming and outgoing states are considered to be free states in the interaction picture, and they exist long before $(t_0 \to -\infty)$ and long after $(t_1 \to \infty)$ the scattering occurs. The operator

$$S = \lim_{t_0 \to -\infty} U_I(t_1, t_0)$$

is given by the time-evolution operator $U_I$ in the interaction picture $U_I(t_1, t_0) = e^{i\hat{H}_0 t_1 / \hbar} e^{-i\hat{H}_1(t_1 - t_0) / \hbar} e^{-i\hat{H}_0 t_0 / \hbar}$, and the above $S$-matrix can be redefined as

$$\langle p | S | k \rangle = \langle p^- | k^+ \rangle.$$

The scattering eigenstates $|k^+\rangle$ and $|p^-\rangle$ evolve in the interaction picture from a free-photon state either in the
The indices \( i_m, o_m \) can take on the values \( L, R \) for \( m = 1, 2, \ldots N \), depending on whether the \( m \)-th incoming or outgoing photon is left-moving or right-moving. The connection of these input and output operators to those in the input-output formalism will become clear in the next subsection.

Shen and Fan (2007a,b) have recently developed a method inspired by the nonperturbative Bethe-ansatz calculation to derive exact scattering eigenstates \( |k^+\rangle \) of a few photons. The incoming and outgoing photon states can be obtained from the scattering eigenstate \( |k^+\rangle \). The dynamics of two photons in this system are very different from those of a single photon, as they become correlated via the collective scattering from the 2LE (Cheng and Kurizki 1993; Deutsch et al. 1992; Rupasov and Yudin 1984a,b). The approach we present treats the atom-photon dynamics in real space, which is particularly convenient for discussing steady-state photon transport from one space-time point to another.

We start with an ansatz for the full scattering eigenstate \( |k^+\rangle \) of \( H \) for a particular unscattered state \( |k\rangle \) of \( H_0 \). The total number of photons \( N \) is conserved during the scattering process when using the rotating-wave approximation. To calculate different amplitudes of the scattering eigenstate, we employ the time-independent Schrödinger equation \( H|k^+\rangle = \hbar \gamma_k (k_1 + k_2 + \ldots + k_N) |k^+\rangle \) with boundary conditions that determine the propagation direction of the incident photons. We now write down an effective representation of \( H \) in real space, where the evolution of the incident photons is more conveniently described. To this end, we take the photon operators in momentum space to be the Fourier transforms of real-space operators, for example

\[
a_{R,k} \equiv \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} dx \, a_R(x) e^{-ikx},
\]

where \( a_R(x) \) annihilates a right-moving photon at position \( x \) (Shen and Fan 2009). Thus, we find an effective real-space Hamiltonian for a 2LE coupled to 1D continuum with linear dispersion,

\[
\frac{H_{\text{eff}}}{\hbar} = -i \int dx \, v_g \left[ a_{R,k}^\dagger(x) \frac{\partial}{\partial x} a_R(x) - a_R^\dagger(x) \frac{\partial}{\partial x} a_{R,k}(x) \right] + (\omega_e - i\gamma)|e\rangle\langle e| + V \left[ (a_{R,0}^\dagger(0) + a_{L,0}^\dagger(0))|g\rangle\langle e| + \text{c.c.} \right].
\]

We assumed here that the coupling \( V_k \equiv V/\sqrt{2\pi} \) is independent of the wavevector \( k \) (the Markov approximation).

The Hamiltonian \( H_{\text{eff}} \) is nonhermitian in the presence of the dissipation term \( \gamma \). In the following, we calculate \( |k^+\rangle \) using the hermitian \( H_{\text{eff}} \) without \( \gamma \), and subsequently replace \( \omega_e \) by \( \omega_e - i\gamma \) in the final results (Rephaeli and Fan 2013).

The incident photons can be injected in the right-moving and/or left-moving channels. The nonequilibrium dynamics can be probed in experiments by measuring the transmission and reflection of photons at the opposite sides of the waveguide. For a side-coupled 2LE, the transmission coefficient is calculated from the number of photons remaining in the incident channel (or channels) after scattering, and the reflection coefficient is determined by counting photons in the opposite channel (or channels) after scattering. For example, the transmission and reflection coefficient for \( N \) right-moving incident photons are respectively

\[
T = \frac{\langle k^+|a_{R,k}^\dagger(x)a_{R,k}(x)|k^+\rangle}{\langle k|a_{R,k}^\dagger(x)a_{R,k}(x)|k\rangle}, \quad R = \frac{\langle k^+|a_{R,k}^\dagger(x')a_{L,k}(x')|k^+\rangle}{\langle k|a_{R,k}^\dagger(x')a_{L,k}(x')|k\rangle},
\]

where the denominators are a measure of the incident photon flux and are independent of \( x, x' \). Here we choose \( x > 0 \) and \( x' < 0 \). Both \( T \) and \( R \) only provide information about average photon transport in the waveguide. Assessing other statistics of the scattered photons, such as fluctuations in the photon number, requires calculating higher-order correlation functions.

We shall now calculate the single-photon and two-photon scattering eigenstates for the Hamiltonian \( H_{\text{eff}} \) following Ros2010a and Zheng et al. 2010.

**Single-photon dynamics:** The states of an incident photon in the right-moving channel is \( |k\rangle = \int dx e^{ikx} a_{R,k}(x)|\varphi\rangle/\sqrt{2\pi} \), where \( |\varphi\rangle \) represents the photon vacuum with the 2LE in the ground state. Considering different scattering processes, we write an ansatz for the scattering eigenstate,

\[
|k^+\rangle = \int dx [g_R(x) a_{R,k}^\dagger(x) + g_L(x) a_{L,k}^\dagger(x) + \delta(x) e_k |e\rangle\langle g||| \varphi\rangle,
\]
where \( g_R(x) \) and \( g_L(x) \) are amplitudes for right-moving and left-moving photons, respectively, and \( e_k \) is the excitation amplitude for the 2LE. Using the Schrödinger equation \( H_{ef}\ket{k^+} = \hbar \nu \ket{k^+} \), we obtain three coupled linear equations for these three unknown amplitudes

\[
\begin{align*}
&v_g(-i \frac{\partial}{\partial x} - k)g_R(x) + V e_k \delta(x) = 0, \\
&v_g(i \frac{\partial}{\partial x} - k)g_L(x) + V e_k \delta(x) = 0,
\end{align*}
\]

\( (\omega_e - i \gamma - v_g k) e_k + V (g_R(0) + g_L(0)) = 0. \)

Their solutions with the boundary conditions \( g_R(x < 0) = e^{ikx}\sqrt{2\pi} / \sqrt{\gamma + \Gamma}, g_L(x > 0) = 0 \) and the continuity relation \( g_R/L(0) = (g_R/L(0^+) + g_R/L(0^-))/2 \) are

\[
\begin{align*}
g_R(x) &= g_k(x) = e^{ikx}\sqrt{2\pi} \left[ \theta(-x) + t_k \theta(x) \right], \\
g_L(x) &= e^{-ikx}\sqrt{2\pi} r_k \theta(-x), \\
e_k &= \frac{1}{\sqrt{\gamma + \Gamma}} \frac{v_g k - \omega_c + i(\gamma + \Gamma)}{v_g k - \omega_c - i(\gamma + \Gamma)},
\end{align*}
\]

where \( \theta(x) \) is the step function. Here \( \Gamma = V^2/\nu \), and we identify 2\( \Gamma \) as the energy relaxation rate of the emitter into the output channels. The transmission amplitude \( t_k \) and reflection amplitude \( r_k \) are given by

\[
t_k = \frac{v_g k - \omega_c + i\gamma}{v_g k - \omega_c - i(\gamma + \Gamma)}, \quad r_k = t_k - 1,
\]

yielding the normalized 1-photon reflection and transmission coefficients

\[
\begin{align*}
R(k) &= |r_k|^2 = \frac{\Gamma^2}{(v_g k - \omega_c)^2 + (\gamma + \Gamma)^2}, \\
T(k) &= |t_k|^2 = \frac{(v_g k - \omega_c)^2 + \gamma^2}{(v_g k - \omega_c)^2 + (\gamma + \Gamma)^2}.
\end{align*}
\]

In the absence of loss (\( \gamma = 0 \)), \( R(k) + T(k) = 1 \), and the 1-photon reflection exhibits a Breit-Wigner-like (Lorentzian) lineshape around the resonance \( v_g k = \omega_c \), as shown in Fig. 4. An incident, resonant photon is totally reflected by the emitter. Thus, a lossless side-coupled emitter behaves as a perfect mirror for propagating photons in a 1D continuum (Shen and Fan 2005a,b).

Several features of these 1-photon lineshapes, including both the real and imaginary parts of \( t_k \) and \( r_k \), were observed in the optical regime in various cavity QED setups (Birnbaum et al. 2005). For example, a 40% reflection of weak coherent light was obtained with microtoroidal cavities interacting with single cesium atoms (Aoki et al. 2009, Dayan et al. 2008), as depicted in Figs. 3(a) and (b). The observation of photon antibunching (Fig. 3(d)) in the reflected signal demonstrated that it was dominated by single photons. The coupling to and from the cavity was implemented with a tapered optical fiber in the so-called overcoupled regime and thus dominated the internal system losses (Aoki et al. 2009). The 1-photon lineshapes were also demonstrated with a photonic crystal nanocavity coupled to a semiconductor QD (Englund et al. 2007, Fushman et al. 2008). In a 1D continuum, strong scattering of single photons by a single emitter was first observed for microwave photons in superconducting circuits by Astafiev et al. (2010a). Similar scattering lineshapes were later observed for microwave and optical photons in various 1D settings (Abdumalikov et al. 2010, Goban et al. 2014, Hoi et al. 2011). This strong scattering of single photons has been exploited to construct various all-optical quantum devices, such as a 1-photon quantum switch (Zhou et al. 2008), quantum memory, and quantum gates (Ciccarello et al. 2012, Koshino et al. 2010, Rosenblum et al. 2015, Zheng et al. 2013).

Two-photon dynamics: The dynamics of two photons strongly coupled to a single emitter in 1D is interesting and nontrivial. A 2LE is saturated by a single resonant photon, and a second photon in the waveguide cannot be absorbed by the excited emitter (Rephaeli and Fan 2012) show that the outcome of the interaction depends on the spectral bandwidth of the second photon’s wavepacket. If the extent of the wavepacket is much longer than the spontaneous emission lifetime (\( \Gamma + \gamma \))\(^{-1} \) of the emitter, the excited emitter first decays to the ground state and then completely reflects the second photon. In the opposite limit of an extremely short wavepacket, the emitter-photon interaction is inhibited, and the second photon is fully transmitted. In both limits, the first and second photons interact independently with the emitter and thus remain uncorrelated. However, for the intermediate regime, the second photon stimulates the relaxation of the emitter to the ground state. The two photons then leave the emitter simultaneously, becoming correlated. This stimulated emission in a 1D continuum is special, as the emission enhancement cannot be entirely attributed to photon indistinguishability, but largely results from the photon correlation generated by the emitter (Rephaeli and Fan 2012).

We shall construct a 2-photon scattering eigenstate in
FIG. 5 (Color online). Reflection of single photons from a coherent-state input by one atom near a microtoroidal cavity. (a) Transmission $T_0(t)$ and (b) reflection $R_0(t)$ of the probe field after averaging over atom transit events with a selection criterion that the sum of the counts over a time interval of $4 \mu s$ is equal to or greater than a threshold count $C_{th}$ shown in the legend of (a). (c), (d) The second-order (intensity) correlation functions $g^{(2)}_{R,R}(\tau)$ for the transmitted and reflected fields. The dip in $g^{(2)}_{R,R}(\tau)$ around $\tau = 0$ indicates anticausrelation in the detection of photons, which is a signature of antibunching and indicates that the field is dominated by single photons. Solid lines are a theoretical calculation described in [Aoki et al. 2009] from which the figure is adapted.

1D that covers all of the above limits. First, we write the incident state for two photons with wavevectors $\mathbf{k} = (k_1, k_2)$ in the right-moving channels

$$|\mathbf{k}\rangle = \int dx_1 dx_2 \phi_k(x_1, x_2) \frac{1}{\sqrt{2}} a_R^\dagger(x_1) a_R^\dagger(x_2) |\varphi\rangle,$$

where $\phi_k(x_1, x_2) = (e^{i k_1 x_1 + i k_2 x_2} + e^{i k_1 x_2 + i k_2 x_1})/(2\sqrt{2}\pi)$. Our ansatz for the 2-photon scattering eigenstate is

$$|\mathbf{k}^+\rangle = \int dx_1 dx_2 (g_{RR}(x_1, x_2) \frac{1}{\sqrt{2}} a_R^\dagger(x_1) a_R^\dagger(x_2)$$
$$+ e_R(x_1) \delta(x_1) a_R^\dagger(x_2) |g\rangle |\varphi\rangle$$
$$+ g_{RL}(x_1, x_2) a_R^\dagger(x_1) a_L^\dagger(x_2)$$
$$+ e_L(x_2) \delta(x_1) a_L^\dagger(x_2) |g\rangle |\varphi\rangle$$
$$+ g_{LL}(x_1, x_2) \frac{1}{\sqrt{2}} a_L^\dagger(x_1) a_L^\dagger(x_2) |\varphi\rangle,$$

where $g_{RR}(x_1, x_2)$, $g_{RL}(x_1, x_2)$ and $g_{LL}(x_1, x_2)$ are 2-photon amplitudes, and $e_R(x_1)$ and $e_L(x_2)$ are amplitudes of right- and left- moving photons with the 2LE in the excited state. These five unknown amplitudes can be found by solving five coupled linear differential equations, obtained from the 2-photon stationary Schrödinger equation, $H_{\text{sc}} |\mathbf{k}^+\rangle = \hbar \omega c (k_1 + k_2) |\mathbf{k}^+\rangle$. One can solve the differential equations with boundary conditions, $g_{RR}(x_1, x_2 < 0) = \phi_k(x_1, x_2)$, $g_{LL}(x_1, x_2 > 0) = 0$, $g_{RL}(x_1 < 0; x_2 > 0) = 0$, and continuity relations for the amplitudes, e.g., $g_{RR}(0, x) = g_{RR}(x, 0) = [g_{RR}(0+, x) + g_{RR}(0-, x)]/2$.

For example, the amplitudes of the right-moving photons in terms of $g_k(x)$ and $e_k$ in Eqs. (12) are

$$g_{RR}(x_1, x_2) = \frac{1}{\sqrt{2}} [g_k(x_1)g_k(x_2) + 2 \frac{\Gamma}{v g} e_k e_k e^{i(k_1 + k_2)x_c}$$
$$e^{i(k_1 + k_2 - 2\omega_c/v g)x/2} e^{-(\gamma + \Gamma)x/v g} \theta(x) \theta(x_2)] + (x_1 \leftrightarrow x_2),$$

$$e_R(x_1) = (g_k(x_1) e_{k_1} + g_k(x_2) e_{k_2}) e_k,$$

where $x_c = (x_1 + x_2)/2$ and $x = x_1 - x_2$. We observe that the second terms in $g_{RR}(x_1, x_2)$ and $e_R(x_1)$ decay to zero with increasing $|x_1 - x_2|$ and $|x_1|$, respectively. These terms are regarded as 2-photon bound states.

Recently, the existence of two-particle bound states in the presence of a localized interaction has been discussed in the contexts of both photon [Liao and Law 2010; Shen and Fan 2007b] and electron transport [Dhar et al. 2008; Nishino et al. 2011]. Because the interaction is spatially confined, energy and momentum can be exchanged and redistributed between the photons (with the constraint of fixed total energy), enabling the development of photon-photon correlations. The correlation strength depends on $\Gamma$. Experimental evidence for the 2-photon bound state appears in second-order correlation measurements and the transmission and reflection coefficients of the scattered fields [Firstenberg et al. 2013; Hoi et al. 2012], which we discuss later.

It is interesting to study the asymptotic behavior (away from the emitter) of the 2-photon scattering eigenstate

$$|\mathbf{k}^{a+}\rangle = \int dx_1 dx_2 [r(x_1, x_2) a_R^\dagger(x_1) a_R^\dagger(x_2)$$
$$+ \frac{e_k}{\sqrt{2}} a_L^\dagger(x_1) a_L^\dagger(x_2) + \frac{t_2(x_1, x_2)}{\sqrt{2}} a_R^\dagger(x_1) a_R^\dagger(x_2)] |\varphi\rangle,$$

where $t_2(x_1, x_2)$, $r_2(x_1, x_2)$ and $r(x_1, x_2)$ are two-photon amplitudes where, respectively, both photons are transmitted, both are reflected, and one is transmitted and the
other reflected. When two degenerate incident photons are resonant with the lossless emitter \((v_g k_1 = v_g k_2 = \omega_c \text{ and } \gamma = 0)\), we find \cite{Shen and Fan 2007a}
\[
t_2(x_1, x_2) = -\frac{1}{\sqrt{2\pi}} e^{2i\omega_c x_1/v_g e^{-\Gamma|x|/v_g}},
\]
\[
r_2(x_1, x_2) = \frac{1}{\sqrt{2\pi}} e^{-2i\omega_c x_1/v_g} (1 - e^{-\Gamma|x|/v_g}),
\]
\[
r(t(x_1, x_2) = -\frac{1}{\pi} e^{i\omega_x x_1/v_g e^{-2\Gamma|x|/v_g}},
\]

Two important points to notice from the above expressions are: (1) the outgoing state is not a product state, and (2) the transmitted photons are \textit{bunched}, whereas the reflected photons are \textit{antibunched}. Here, the separation \(x\) between the two scattered photons is equivalent to a time delay between them. When plotted versus \(x\) in Fig. 6, \(t_2(x_1, x_2)\) shows a cusp, and \(r_2(x_1, x_2)\) shows a dip at \(x = 0\). For a side-coupled 2LE, since \(r_2(x_1, x_2)\) arises entirely from emission without any contribution from the incident photons, the antibunching in \(r_2(x_1, x_2)\) confirms that a single emitter cannot simultaneously emit two photons. On the other hand, the behavior of \(t_2(x_1, x_2)\) and \(rt(x_1, x_2)\) involves interference between the incident and emitted photons. The behavior of \(r_2(x_1, x_2)\) and \(t_2(x_1, x_2)\) in Fig. 6 agree qualitatively with the experimentally measured 2-photon correlations \(g^{(2)}(r)\) of reflected and transmitted photons, shown in Figs. 3(c,d) and 12 for optical and microwave photons.

An exact multiphoton scattering state for 2LEs \cite{Zheng et al. 2010}, and multilevel emitters \cite{Roy and Bondyopadhaya 2014, Zheng et al. 2012} has been derived, extending the above scattering theory. Multiphoton bound states appear in these multiphoton scattering states. The ‘brute force’ technique we have used for constructing the scattering eigenstates becomes much more laborious with increasing photon number \(N\), as the possible scattering configurations rapidly increase. An efficient method to describe the evolution of an arbitrary initial state of the present system has been developed by Yudson and Reineke \cite{2008} using the algebraic Bethe ansatz. This elegant method avoids both the difficulty of following numerous configurations and the subtle problems of normalization and completeness of states. However, with increasing photon number it becomes very difficult to extract useful information from these exact multiphoton scattering states, whether calculated using the algebraic Bethe ansatz or scattering theory.

\textit{Coherent state input:} Coherent states are an important class of multiphoton states, describing the output of both an ideal laser and a microwave generator. They are thus commonly used as an input in experiments. Zheng \textit{et al.} \cite{2010} formulated the scattering of a weak coherent-state wave-packet by a 2LE using the S-matrix in scattering theory. The incident wave-packet is \(|\alpha\rangle = e^{a_R^\dagger \bar{n} \frac{\bar{n}}{2}}|\varphi\rangle\), where \(\bar{n} = \int dk |\alpha(k)|^2\) is the mean photon number, which is kept small \(\bar{n} \leq 1\) to observe few-photon behavior.

For a coherent-state wave-packet, the photon statistics are Poissonian, implying that the variance of the photon number is also \(\bar{n}\). Here \(a_R^\dagger = \int dk \alpha(k) a_R^\dagger(k)\) for an incident wave-packet from the left. We employ a Gaussian wave-packet \cite{Zheng \textit{et al.} 2010}
\[
\alpha(k) = \frac{\sqrt{\pi}}{(2\Delta k)\bar{n}^{1/4}} \exp (-\frac{(k - k_0)^2}{4\Delta k^2}),
\]
with width \(\Delta k\) and mean momentum \(k_0\). The scattered state can be expressed as \(|\psi_\text{out}\rangle = \sum_N S^{(N)}(\alpha)|\alpha\rangle\), where \(S^{(N)}\) is the S-matrix operator of \(N\) incident photons, whose elements can be calculated using scattering theory. For example, \(S^{(0)} = |\varphi\rangle \langle \varphi|\)
\[
S^{(1)} = \int dk \, t_k a_R^\dagger k |\varphi\rangle \langle a_R k | + \int dk \, r_k a_R^\dagger k |\varphi\rangle \langle a_R k |
\]
where \(t_k\) and \(r_k\) are the 1-photon transmission and reflection amplitudes of Eq. 13. Following this prescription, we find the transmission of a weak coherent state input
\[
T(k_0, \Delta k) = \frac{\langle \psi_\text{out} | a_R^\dagger k(x) a_R(x) | \psi_\text{out} \rangle}{\langle a_R^\dagger k(x) a_R(x) | \alpha \rangle}
\]
\[
= \int dk_1 dk_2 \alpha(k_1) \alpha(k_2) t_{k_1} t_{k_2}^* e^{i(k_1 - k_2)x} \int dk_1 dk_2 \alpha(k_1) \alpha(k_2) e^{i(k_1 - k_2)x} - (23)
\]
where \(x > 0\), and we have kept only the leading order contribution coming from single-photon scattering. For a long, monochromatic pulse (\(\Delta k \ll \Gamma + \gamma\)), the coefficient \(T(k_0, \Delta k)\) reduces to the single-photon transmission coefficient \(T(k_0)\) in Eq. 15.

In experiments, the statistics of scattered photons is predominately determined by measuring second-order correlations of the scattered fields. For the transmitted beam, it is defined as
\[
g^{(2)}(x_1, x_2) = \frac{\langle \psi_\text{out} | a_R^\dagger(x_1) a_R^\dagger(x_2) a_R(x_2) a_R(x_1) | \psi_\text{out} \rangle}{\prod_{i=1}^N \langle \psi_\text{out} | a_R^\dagger(x_i) a_R(x_i) | \psi_\text{out} \rangle}.
\]
By neglecting the contributions from $N \geq 3$ photons in $|\psi^{\text{out}}_n\rangle$ for $n \leq 1$, Zheng et al. (2010) have found
\begin{equation}
 g^{(2)}(x_2 - x_1) = \frac{1}{\sqrt{2\pi}} \int dk_1dk_2 \alpha(k_1)\alpha(k_2)(\langle \sigma \alpha(k_1)\sigma \alpha(k_2)\rangle - \langle \sigma \rangle^2). \quad (24)
\end{equation}
Here again, the distance separation can be converted to time separation via $\tau = (x_2 - x_1)/v_g$, which is what is typically measured in experiments. The first and second terms in the numerator of Eq. (24) are related respectively to the noninteracting and the bound-state parts of the 2-photon wavefunction. Without the bound-state contribution (i.e., no effective photon-photon interaction), $g^{(2)}(x_2 - x_1) = 1$. In the presence of the bound state, $g^{(2)}(x_2 - x_1)$ can show bunching and antibunching of the transmitted photons at different values of the coupling rate $\Gamma$, as shown in Fig. 7. Note that the observability of these effects also depends on having the appropriate value of $\Gamma/\gamma$. For very strong coupling $\Gamma/\gamma \gg 1$, $g^{(2)}(x_2 - x_1)$ of the transmitted photons always shows bunching [Fig. 7(c)] and was observed by Hoi et al. (2012). For very weak coupling $\Gamma/\gamma \ll 1$, $g^{(2)}(x_2 - x_1)$ is nearly featureless, exhibiting only a small antibunching dip [Fig. 7(a)]. In the intermediate regime $\Gamma/\gamma \approx 1$, the antibunching is more pronounced [Fig. 7(b)].

**B. Input-output formalism**

The input-output formalism is a celebrated technique for analyzing the effect of light-matter interactions on the quantum statistics of light fields (Gardiner and Collett 1985, Walls and Milburn 2008). Based on the Heisenberg picture, it allows one to study the time evolution of the field operators, with the ability to account for various input field states, for example, coherent states, Fock states or squeezed states. Fan et al. (2010) recently adopted this formalism to investigate the few-photon scattering by emitters in a 1D continuum, relating it to the scattering theory of correlated photons.

**Equations of motion:** Essentially, given a Hamiltonian $H$, one uses the Heisenberg picture to derive a set of nonlinear differential equations for the time evolution of the input and output fields $b_{m,\text{in}}(t)$, $b_{m,\text{out}}(t)$ of left-moving ($m = L/+ \rightarrow R$) and right-moving ($m = R/- \rightarrow L$) photons,
\begin{equation}
b_{m,\text{in}}(t) = \frac{1}{\sqrt{2\pi}} \int dk a_{m,k}(t_0)e^{i\nu_{m,k}(t_0-t_0)}, \quad (25)
b_{m,\text{out}}(t) = \frac{1}{\sqrt{2\pi}} \int dk a_{m,k}(t_1)e^{i\nu_{m,k}(t_1-t_0)}, \quad (26)
\end{equation}
where $a_{m,k}(t_0) = e^{iH_{0}/\hbar}a_{m,k}e^{-iH_{0}/\hbar}$ and $a_{m,k}(t_1) = e^{iH_{1}/\hbar}a_{m,k}e^{-iH_{1}/\hbar}$ are Heisenberg operators in the limits $t_0 \rightarrow -\infty$, $t_1 \rightarrow \infty$. For clarity, we will use $b, b^\dagger$ for operators in the input-output formalism and $a, a^\dagger$ for operators in scattering theory. The input-output operators are directly related to the operators that create and destroy incoming and outgoing scattering eigenstates in scattering theory [see Eqs. (8) and (9)]. For example,
\begin{align*}
b_{R,\text{in}}(t) &= \frac{1}{\sqrt{2\pi}} \int dk e^{iH_{0}/\hbar}a_{R,k}e^{-iH_{0}/\hbar}e^{-i\nu_{k}(t-t_0)} \\
&= \frac{1}{\sqrt{2\pi}} \int dk e^{iH_{0}/\hbar}e^{-iH_{0}/\hbar}a_{R,k}e^{iH_{0}/\hbar}e^{-i\nu_{k}(t)} \\
&= \frac{1}{\sqrt{2\pi}} \int dk a_{R,\text{in}}(k)e^{-i\nu_{k}}, \quad (27)
\end{align*}
where in the second line we replaced $a_{R,k}e^{-i\nu_{k}t}$ with $e^{-iH_{0}/\hbar}a_{R,k}e^{iH_{0}/\hbar}$ by employing $[H_{0},a_{R,k}] = -\nu_{k}a_{R,k}$. Thus, $a_{m,\text{in}/\text{out}}(k)$ gives the spectral representation of $b_{m,\text{in}/\text{out}}(t)$. Using relations similar to (27), we can rewrite the $S$-matrix elements in Eq. (7) as
\begin{equation}
S^{(N)}_{p,k} = \langle p|S|k\rangle \quad (28)
\end{equation}
where we use a global Fourier transform $F \mathcal{F}^{(2N)} = (2\pi)^{-N} \int \prod_{j=1}^{N} dt_j d\epsilon_j e^{i\nu_{\epsilon_j}(t_j-t_{j-1})}$ with $\epsilon_{j-1} = -(R,-L)$ to relate the $S$-matrix in linearized momentum (or frequency) and time. We shall now show how the $S$-matrix elements are found within the input-output formalism.

To simplify the presentation, we slightly rewrite the emitter part in the Hamiltonian $H$ using Pauli matrices. We write the full Hamiltonian for a single 2LE side-coupled to a 1D continuum as
\begin{align*}
H_{0} &= \int_{-\infty}^{\infty} dk v_g k a_{R,k}^\dagger a_{R,k} - \frac{1}{2}\omega_c \sigma_z + V \mathcal{F}^{(2N)} \langle p|a_{R,k}^\dagger a_{R,k}\rangle \sigma_+ + \langle a_{R,k}^\dagger a_{L,k}\rangle \sigma_- \quad (29)
\end{align*}
where $\sigma_\pm$ are raising and lowering operators for the 2LE and $\sigma_z = 2\sigma_+\sigma_- - 1$. Here $\omega_c$ is again the transition energy of the 2LE, and we have dropped the inelastic loss term $i\gamma$. We again assume that the coupling $V$ to the linearized modes is independent of the wavevector $k$.

One can write Heisenberg equations of motion for the operators in Eq. (29) and define input-output operators for the fields, as illustrated in detail for a chiral model in Appendix A. One then gets
\begin{align*}
b_{R,\text{out}}(t) &= b_{R,\text{in}}(t) - i\frac{V}{v_g}\sigma_-(t) \\
b_{L,\text{out}}(t) &= b_{L,\text{in}}(t) - i\frac{V}{v_g}\sigma_-(t), \quad (30)
\end{align*}
again denoting $\Gamma = V^2/v_g$. We now have all the required tools to study the scattering of photons in this system.

**Scattering properties:** The $S$-matrix is a fundamental tool to calculate the scattering properties. For a single,
right-moving input photon, the transmission amplitude is given by the following element of the S-matrix
\[
\langle \varphi | a_{R,\text{out}}(p) a_{R,\text{in}}^\dagger(k) | \varphi \rangle = \frac{1}{\sqrt{2\pi}} \int dt \langle \varphi | b_{R,\text{out}}(t) | k^+ \rangle e^{iv_g pt},
\]
(31)
where we use \(a_{R,\text{in}}^\dagger(k) | \varphi \rangle = | k^+ \rangle \) [see Eq. (34)] and write \(a_{R,\text{out}}(p) \) in terms of \(b_{R,\text{out}}(t) \). We therefore need to calculate \(\langle \varphi | b_{R,\text{out}}(t) | k^+ \rangle \) to find the 1-photon transmission amplitude. It can be obtained by sandwiching Eqs. (30) between \(| \varphi \rangle \) and \(| k^+ \rangle \),
\[
\langle \varphi | b_{R,L,\text{out}}(t) | k^+ \rangle = \langle \varphi | b_{R,L,\text{in}}(t) | k^+ \rangle - i V \langle \varphi | \sigma_- (t) | k^+ \rangle,
\]
(32)
\[
\frac{d}{dt} \langle \varphi | \sigma_- (t) | k^+ \rangle = - (i \omega_c + \Gamma) \langle \varphi | \sigma_- | k^+ \rangle + i V \langle \varphi | \sigma_+(t) (b_{R,L,\text{in}}(t) + b_{L,\text{in}}(t)) | k^+ \rangle.
\]
(33)
One can easily find some parts of the above expressions,
\[
\langle \varphi | b_{R,L,\text{in}}(t) | k^+ \rangle = \langle \varphi | b_{L,\text{in}}(t) a_{R,\text{in}}^\dagger(k) | \varphi \rangle = e^{-iv_g kt},
\]
\[
\langle \varphi | b_{L,\text{in}}(t) | k^+ \rangle = \langle \varphi | b_{L,\text{in}}(t) a_{R,\text{in}}^\dagger(k) | \varphi \rangle = 0,
\]
\[
\langle \varphi | \sigma_+(t) b_{R,L,\text{in}}(t) | k^+ \rangle = - \langle \varphi | b_{R,L,\text{in}}(t) | k^+ \rangle,
\]
(34)
where \(\sigma_- | \varphi \rangle = - | \varphi \rangle \), as \(| \varphi \rangle \) is the photon vacuum state with the 2LE also in its ground state. Plugging the results of Eqs. (34) into Eq. (33), we obtain a first-order inhomogeneous differential equation with the solution
\[
\langle \varphi | \sigma_- | k^+ \rangle = \frac{e^{-iv_g kt}}{\sqrt{2\pi}} V \frac{1}{v_g k - \omega_c + i \Gamma},
\]
(35)
\[
\langle \varphi | b_{R,L,\text{out}}(t) | k^+ \rangle = \frac{i \tilde{t}_k e^{-iv_g kt}}{\sqrt{2\pi}}.
\]
(36)
Here \(\tilde{t}_k = t_k (\gamma = 0)\) is the 1-photon transmission amplitude ignoring decoherence and photon loss. Finally, inserting Eq. (36) in Eq. (31), we arrive at
\[
\langle \varphi | a_{R,\text{out}}(p) a_{R,\text{in}}^\dagger(k) | \varphi \rangle = \tilde{t}_k \delta(k - p).
\]
(37)
Similarly, we can derive the 1-photon reflection amplitude \(\tilde{r}_k = \tilde{r}_k - 1 \) from the S-matrix element
\[
\langle \varphi | a_{L,\text{out}}(p) a_{R,\text{in}}^\dagger(k) | \varphi \rangle = \tilde{r}_k \delta(k + p).
\]
We thus see that the 1-photon scattering amplitudes obtained here are the same as those we found using scattering theory.

We note that the same result can also be arrived at by directly approximating \(\sigma_- = -1\) in Eqs. (30), thus linearizing the operator equations. Such an approximation is commonly used in many quantum optics calculations in the weak-excitation limit by considering the 2LE to be mostly in its ground state. Physically, the weak-excitation limit is valid for 1-photon scattering when the 1-photon wavepacket has a much longer duration than the lifetime of the 2LE. However, the weak-excitation limit is not always valid, even for a 1-photon pulse (Rephaeli et al. 2010).

Similar derivations of the elements of the S-matrix are carried out for multiphoton Fock states (Fan et al. 2010; Rephaeli et al. 2011; Xu et al. 2013) as well as for coherent state inputs (Koshino and Nakamura 2012; Peropadre et al. 2013). Input-output theory can also be easily extended using the master equation formalism to include decoherence processes such as pure dephasing, which dominates in superconducting systems (Koshino and Nakamura 2012; Peropadre et al. 2013). Finally, the input-output formalism has been recently extended to investigate scattering of multiple photons by multiple interacting and noninteracting emitters in a 1D continuum (Caneva et al. 2015; Xu and Fan 2015). We discuss these in the next section.

C. Other theoretical techniques

Until now we have discussed scattering of photons in a 1D continuum with a linearized dispersion relation and the Markov approximation. However, there are examples where the linearization is a poor approximation, and the nonlinearity gives rise to important physical behavior (Longo et al. 2010; Roy 2011a, Zhou et al. 2008). One such case is of coupled resonator arrays, exhibiting a tight-binding dispersion relation that is strongly nonlinear. These structures were realized in photonic crystals (Nakomi et al. 2008) and proposed in superconducting systems (Zhou et al. 2008).

For a sinusoidal tight-binding dispersion, the Hamiltonian in Eqs. (1) and (2) can be rewritten as
\[
\frac{H_{\text{TB}}}{\hbar} = -J \sum_{x=-\infty}^{\infty} (a_{x+1}^\dagger a_x + a_x^\dagger a_{x+1}) + (\omega_c - i \gamma) b^\dagger b + V_0 (a_0^\dagger b + b^\dagger a_0) + \frac{U}{2} b^\dagger b (b^\dagger b - 1),
\]
(38)
where \(a_0^\dagger\) and \(b^\dagger\) create a photon at site \(x\), and \(J\) is the hopping rate between nearest neighbor sites. Here, the 2LE is replaced by an additional bosonic site, side-coupled at \(x = 0\) (Longo et al. 2010; Roy 2011a). The photon creation operator at the additional site is \(b^\dagger\). The states of 0 and 1 photon correspond respectively to the ground and the excited states of the 2LE in Eq. (1), whereas the forbidden ‘multiphoton’ occupancy of the 2LE is avoided by introducing the interaction term \(U b^\dagger b (b^\dagger b - 1)/2\) and taking the limit \(U \to \infty\).

Scattering eigenstates for one and two photons can be derived exactly for the Hamiltonian in Eq. (38) using the Lippmann-Schwinger equation. Roy (2011a) compares 1-photon and 2-photon transmission for linear and (nonlinear) tight-binding dispersion relations and points out the effect of band edges on the 2-photon transmission. Here again, the 2-photon scattering eigenstates exhibit...
bound states due to inelastic exchange of photons. A unique feature of this approach is the ability to exactly calculate 2-photon scattering states for multiple emitters separated by arbitrary distances (Zheng and Baranger 2013), similarly to the calculation of multiple quantum impurities (Roy 2010b). Furthermore, one can numerically study 2-photon scattering by multilevel emitters. Longo et al. (2010) investigate the scattering of few-photon states in 1D lattice models using numerical time-dependent wave-packet evolution. This framework allows one to analyze both the dynamics of multiphoton wave packets that interact with the emitter and the dynamics of the emitter itself. Employing the approach of density matrix renormalization group (DMRG), they extend their study for 3-photon and 4-photon transport. They note is based on the Lehmann-Symanzik-Zimmermann reduction, a method to calculate S-matrix elements from multiparticle scattering processes, which leads to radiative trapping at the emitter. Another study worth noting is based on the Lehmann-Symulzik-Zimmermann reduction, a method to calculate S-matrix elements from the time-ordered correlation functions. This approach is employed by Shi and Sun (2009) to investigate multiphoton S-matrices in various complex quantum networks of propagating photons coupled to emitters.

D. Three-level emitter: a single-photon router

A single-photon router can route one photon from an input port to either of two output ports, while conserving the superposition of input photonic states. It thus finds important applications in optical quantum networks. Building on the work of Abdumalikov et al. (2010), Hoi et al. (2011) demonstrated that a driven three-level emitter (3LE) strongly coupled to a 1D continuum can act as an efficient single-photon router. Chang et al. (2007), Neumeier et al. (2013), Shomroni et al. (2014). As we shall see, the presence or absence of a classical control field in this system determines a specific output port for the probe photon.

We consider a 3LE with either the Λ or ladder-type structures in Fig. 8 with the probe light tuned to the |g⟩−|e⟩ transition. A classical light field drives the |e⟩−|s⟩ transition with a Rabi frequency Ωc and frequency detuning Δc. The Hamiltonian describing the system

$$\frac{H_R}{\hbar} = \frac{H_{eff}}{\hbar} + (\omega_c + \Delta_c - i \gamma_s)|s\rangle\langle s| + \frac{\Omega_c^2}{2}(|s\rangle\langle e| + |e\rangle\langle s|),$$

extends the Hamiltonian $H_{eff}$ of the 2LE in Eq. (10). Losses from the state |s⟩ are accounted for by the imaginary term $-i \gamma_s$. With natural atoms, |g⟩ and |s⟩ can be two different Zeeman states, and the transitions |g⟩−|e⟩ and |e⟩−|s⟩ would couple to different optical polarizations based on selection rules.

Witha and Sørensen (2010) and Roy (2011b) study the transmission and reflection line-shapes for the Λ-type system. The 1-photon transmission and reflection amplitudes are given respectively by $t'_k = \chi/(\chi + i \Gamma)$ and $r'_k = -i \Gamma/(\chi + i \Gamma)$ [see, e.g., Roy and Bondyopadhyaya (2014) for a derivation], where again $\Gamma = V^2/\nu_g$ and

$$\chi = \Delta + i \gamma - \frac{\Omega_c^2}{4(\delta + i \gamma_s)}.$$  

Here $\Delta = \nu_g k - \omega_c$ is the detuning of the incident probe photon from the |g⟩−|e⟩ transition, and $\delta = \Delta - \Delta_c$ is the Raman detuning. We plot in Fig. 9 the transmission coefficient $T'(k) = |t'_k|^2$ for different values of the parameters. In the absence of the control field, the probe photon is reflected due to the |g⟩−|e⟩ transition [Fig. 9(a)], whereas in the presence of a control, when $\Omega_c^2 \gtrsim \Gamma \gamma_s$, a transmission window appears at the Raman resonance $\Delta = \Delta_c (\delta = 0)$ [Figs. 9(b-d)].

Two parameter regimes are of interest. In the first regime, predominantly characterizing atomic Λ-systems, the |s⟩ state is metastable and much longer lived than the |e⟩ state, that is $\gamma_s \ll \gamma, \Gamma$. This yields a narrow transmission window within the broader reflection or absorption line, an effect known as electromagnetically induced transparency (EIT) (Boiler et al. 1991, Fleischhauer et al. 2005, Harris et al. 1990). Intuitively, EIT results from a destructive interference between two allowed transitions, leading to cancellation of the population of |e⟩ and to formation of a ‘dark state’. With increasing strength of the control field, the width of the transparency window increases, as shown in Fig. 9(c).

In the second regime, generally characterizing superconducting ladder systems, |s⟩ is shorter lived than |e⟩ due to population relaxation, as the |s⟩−|e⟩ transition also couples strongly to the transmission line. Therefore $\gamma_s \gtrsim \gamma, \Gamma$, and narrow EIT lines cannot be obtained. Rather, stronger control fields $\Omega_c \gg \Gamma$ are needed to drive the |s⟩−|e⟩ transition and open a transparency window (Anisimov et al. 2011), an effect known as the Autler-Townes splitting (ATS). The width of the transmission window due to ATS is $\Omega_c$, as shown in Fig. 9(d). In both regimes, a sufficiently strong control field allows the probe photons to pass the emitter without being re-
flected. Thus, the presence or absence of a control field determines the route of the probe photon.

The recent experiments by Abdumalikov et al. (2010) and Hoi et al. (2011) used a ladder-type superconducting qubit and observed transparency windows due to ATS, as shown in Figs. 10(a,b). By tuning the control field, Hoi et al. (2011) demonstrated the routing of a single-photon probe. Since both relaxation and dephasing are important in superconducting systems, a generalized model was introduced by Abdumalikov et al. (2010) to describe the experiments, replacing the effective non-Hermitian Hamiltonian with a Markovian master equation for the density matrix. The transmission spectra calculated by Abdumalikov et al. (2010) are shown in Figs. 10(c,d) and are similar to our $t'_k$ given above [with their loss terms $\gamma_{21}$ and $\gamma_{31}$ corresponding roughly to our $(\gamma + \Gamma)$ and $\gamma_s$, respectively].

Recently, more complicated superconducting systems have been used to make effective A-systems. Inomata et al. (2014) realized an effective “impedance-matched” A-type emitter using dressed states of a driven superconducting qubit-resonator system. Novikov et al. (2016) demonstrated EIT in a superconducting circuit using the Jaynes-Cummings dressed states of a strongly coupled qubit-cavity system as an effective A-system.

Photon-photon correlations have also been calculated for 3LE systems (Li et al. 2015). To do this, one needs to derive the multiphoton scattering states for the system. Roy (2011b) derive the 2-photon scattering state of the probe field for a 3LE weakly driven by a control field. An exact 2-photon scattering state for an arbitrary strength of $\Omega_c$ is calculated by Roy and Bondyopadhyaya (2014) and Zheng et al. (2012). Roy and Bondyopadhyaya (2014) show that the second-order correlation of the transmitted photons near the Raman resonance changes from bunching to antibunching to constant, as the strength of the control field is ramped up from zero to a higher value where the ATS appears.

E. Superconducting circuits

While proposed in a variety of experimental systems, the strong coupling of propagating light to matter was first demonstrated in a circuit QED setting, with superconducting qubits playing the role of artificial atoms (Astafiev et al. 2010a). The major advantage of these types of systems in achieving strong coupling is that the electromagnetic fields can be tightly confined into quasi-1D superconducting waveguides ($v_g \sim c/3$). In a typical implementation, the lateral dimensions are of order 10 microns while the corresponding wavelength is of order 10 mm. (In the direction of propagation, the light is unconfined.) The mode volume is then $\sim 10^{-6} \lambda^3$, compared to $\sim 1\lambda^3$ for optical systems, implying strongly enhanced electric field strengths. It is, furthermore, straightforward to fabricate superconducting qubits with dipole moments in this range (Wallraff et al. 2004), meaning that efficient mode matching can be easily accomplished. These were the key insights leading to the rapid growth of experimental work in this field.

These systems work in the microwave regime. In this frequency range ($\sim 5$ GHz), where the photon energy $\hbar \omega$ is well below the superconducting gap energy $\Delta_{sc}$, superconductors have very little loss, which protects the coherence of the circuits. In aluminum for instance, $\Delta_{sc}/\hbar \approx 50$ GHz. At optical frequencies ($\hbar \omega \gg \Delta_{sc}$), metals
are not superconductors and are very lossy. Therefore, metallic waveguides are not useful in confining optical light at these size scales. The trade-off is that these microwave systems must be operated at very low temperatures, typically below 50 mK, in order for the background thermal (blackbody) field to be sufficiently suppressed.

The first demonstration of the strong scattering of propagating microwave light by a single artificial atom was achieved by Astafiev et al. (2010a) from the NEC Corporation group (see Fig. 11). They observed a strong extinction of the transmitted light corresponding to $1 - T = 94\%$. This was the first time that the hallmark result of $1 - T > 50\%$ was achieved for a single scatterer in any type of system, clearly separating the coherent and incoherent scattering regimes. They also derived reflection ($r$) and transmission ($t$) amplitudes of an incident coherent state using input-output theory and the master equation approach to treat decoherence:

$$ r = r_0 \frac{1 + i\Delta/\Gamma_2}{1 + (\Delta/\Gamma_2)^2 + \Omega^2/\Gamma_1\Gamma_2}, \quad t = 1 - r, \quad (41) $$

with $r_0$ the maximal reflection amplitude and $\Omega$ the Rabi frequency of the incident probe. The rate $\Gamma_2 = \Gamma_1/2 + \Gamma_ϕ$, where $\Gamma_1$ is the energy relaxation rate and $\Gamma_ϕ$ is the pure dephasing rate. Note that there is a sign difference in the definition of reflection amplitude in Eq. (41) and Astafiev et al. (2010a). For superconducting systems, the rate of emission into spurious modes is negligible, implying $\Gamma_1 = 2\Gamma_ϕ$. For weak driving ($\Omega \ll \Gamma_1, \Gamma_2$), Eq. (41) agrees with Eq. (14) if we further identify $\Gamma_ϕ = \gamma$. We note again that this is a typical distinction between atomic and superconducting systems, that is, in the superconducting systems we consider here, emission into spurious modes is negligible while pure dephasing is significant.

The NEC group demonstrated a number of prototypical atomic physics effects using their artificial atom including resonance fluorescence of the Mollow triplet (Astafiev et al., 2010a) and induced transparency due to the Autler-Townes splitting (Abdumalikov et al., 2010) as discussed before. These results demonstrated that the quality of coherence in superconducting qubits had become sufficiently high for them to genuinely be considered “artificial atoms.” NEC’s work was reproduced by the Chalmers group, who improved the scattering efficiency by more than an order of magnitude by increasing the coupling strength, achieving $1 - T = 99.4\%$ (Hoi et al., 2013b, 2011).

Importantly, the simple measurement of the coherent scattering properties at single-photon probe powers can be fully explained by a classical model of scattering from a harmonic oscillator, i.e., an LC circuit. Essentially, as long as the probe only weakly excites the atom from the ground state, it does not obtain information about the presence of higher levels and cannot distinguish between a two-level and a multilevel system. To rule out that the observed signal is purely classical, we must look beyond the linear response of the system. The experiments mentioned above which involve stronger probes and nonlinear response, such as the resonance fluorescence experiment, are not simply explained by a classical model of the emitter. Still, they tell us very little about the state of the scattered electromagnetic field.

As we have shown theoretically, the light scattered by a single emitter should be distinctly nonclassical, which can be characterized by higher-order correlation measurements. The Chalmers group measured the second-order correlation function $g^{(2)}(\tau)$ of the scattered field and showed that it was significantly less than 1 (Hoi et al., 2012). The essential idea is that the emitter can only scatter one photon at a time, so it only reflects the 1-photon component of the input coherent state, while transmitting the higher photon number components. The reflected state is then a superposition of only the vacuum and the 1-photon state, which exhibits photon antibunching as shown in Fig. 12. The antibunching behavior reveals the quantum nature of the scattered field (Kimble et al., 1977; Paul, 1982).

These circuits have also been explored in terms of possible applications for quantum communication networks. One broad architecture of a network imagines quantum nodes, which perform basic processing tasks, connected by long-distance channels carrying quantum information (Kimble, 2008). By far, the leading candidates for implementing quantum channels involve optical or telecom photons propagating in fibers or free space. A number of physical systems are being actively investigated for implementing quantum nodes, including resonance fluorescence of the Mollow triplet (Astafiev et al., 2010a) and induced transparency due to the Autler-Townes splitting (Abdumalikov et al., 2010) as discussed before. These results demonstrated that the quality of coherence in superconducting qubits had become sufficiently high for them to genuinely be considered “artificial atoms.” NEC’s work was reproduced by the Chalmers group, who improved the scattering efficiency by more than an order of magnitude by increasing the coupling strength, achieving $1 - T = 99.4\%$ (Hoi et al., 2013b, 2011).

Using the architecture described above, the Chalmers group has already demonstrated a number of prototype
FIG. 12 (Color online). Second-order correlation function $g^{(2)}(\tau)$ versus the time separation $\tau$ between the photons for a thermal state, a coherent state, and the scattered states generated by the artificial two-level emitter. (A) $g^{(2)}(\tau)$ of a thermal state and a coherent state. (B) $g^{(2)}(\tau)$ of the resonant transmitted microwaves for four different incident powers. (C) $g^{(2)}(\tau)$ of a resonant reflected field for two different incident powers. $g^{(2)}(0)$ does not reach zero because of well-understood experimental imperfections, including the bandwidth of the measurement system. (D) $g^{(2)}(\tau)$ of a resonant reflected field for different measurement bandwidths (BW), illustrating how decreasing bandwidth decreases the depth of the dip. The solid curves in (A)-(D) are theory curves. Adapted from Hoi et al. (2012).

elements for quantum nodes. In the first experiment, as mentioned earlier, they demonstrated a router that exploited the ATS to direct a microwave input at the single-photon level between two ports (Hoi et al., 2011). The on-off ratio of the router was 99% with a switching time of a few nanoseconds. The ability to produce nonclassical light, which is a required resource for a quantum network, by scattering classical light from a purely passive device as described above (Hoi et al., 2012) also has potential technological applications. This can be considered as a “quantum-state filter” that accepts a desired portion of the input state (the 1-photon component) and rejects the rest (the higher photon numbers). We compare this to a conventional frequency filter that accepts a desired set of frequencies while rejecting others. More advanced quantum-state filters, containing multiple qubits, could be an economical way to produce nonclassical light for quantum networks.

In a separate experiment, the Chalmers group demonstrated that the single qubit worked as a highly effective cross-Kerr medium (Hoi et al., 2013a). The cross-Kerr effect is essentially an effective interaction between light at two different frequencies mediated by a nonlinear medium (Shen, 1984). The basic effect is that the presence of one beam induces a phase shift in the other beam that is proportional to intensity. The cross-Kerr effect has been studied extensively in the past as a possible route to, e.g., quantum nondemolition measurements (QND) of single photons (Muro et al., 2005) and photonic gates (Milburn, 1989; Turchette et al., 1995). However, the strength of the cross-Kerr effect is generally too weak in bulk nonlinear crystal for any of these applications to be realizable. In the Chalmers experiment, by contrast, the bulk nonlinear medium is replaced by a single 3-level (artificial) atom, and the two input fields are tuned to the $|g\rangle - |e\rangle$ and the $|e\rangle - |s\rangle$ transition frequencies. The experiment was performed with coherent states, demonstrating an average cross-Kerr phase shift of 20° per photon, surpassing the previous state-of-the-art of 0.01° per photon for propagating light (Matsuda et al., 2009; Perrella et al., 2013; Venkataraman et al., 2013). In parallel, a phase shift of 45° was demonstrated with Rydberg atoms, as discussed in Sec. IV.

This work on the cross-Kerr effect has stimulated a great deal of theoretical work analyzing the prospects of this system to be used for the QND detection of photons. Interestingly, a first work concluded that QND detection could not be achieved with a single atom, due to atomic saturation effects (Fan et al., 2013). Because a bulk nonlinear crystal can largely be considered as an incoherent ensemble of such atoms, this work strongly suggests that QND detection is not possible in a bulk system, which was an important general result. However, subsequent work has shown that careful arrangements of multiple atoms, sequentially interacting with the propagating photon, can achieve QND detection of a single propagating photon (Fan et al., 2014; Sathyamoorthy et al., 2014).

The Chalmers group has also looked at a system with one atom in front of a “mirror” (Hoi et al., 2015). In this case, the mirror-like boundary condition is created by simply terminating the transmission line with a short circuit to ground at one end. The effective separation is modulated around the value of $\lambda/2$. Interference between the input field, the field scattered by the atom and the field reflected by the mirror creates a standing wave pattern. When the separation is exactly $\lambda/2$, the atom sits at a node of the field, and it is effectively hidden from the probe. This can be thought of as an interaction between the atom and its image in the mirror, much in the same way that the two real emitters interact in the Zürich experiment (van Loo et al., 2013) described below. Interestingly, it was shown that the atom not only hides from the classical probe field, but also from vacuum fluctuations, with a suppression of the free-space relaxation rate by a factor of 50 being observed. In contrast to the Purcell effect, where a cavity can be used to suppress the relaxation rate, the suppression achieved through this novel form of vacuum engineering occurs even though the atom is coupled to a continuum of propagating states.

While superconducting circuits interacting with microwave photons show great promise for implementing quantum nodes, the implementation of long-distance
quantum channels using optical photons is very far advanced, with records distances of > 100 for free-space and in-fiber transmissions (Korzh et al., 2015; Ursin et al., 2007). This state of affairs has motivated considerable work in recent years towards the development of a quantum interface between microwave and optical photons. The fundamental difficulty is the several orders of magnitude that separate the energy scales of these two classes of photons. A number of research groups have attempted to bridge this gap in a wide variety of physical systems. One common approach is to use ensembles of dopant atoms in a host crystal, taking advantage of the fact that specific transition can be excited both through microwave and optical transitions. Ensembles are used to enhance the coupling to single photons. A number of different systems are being studied including nitrogen-vacancy centers in diamond (Amsüss et al., 2011; Grezes et al., 2014; Julsgaard et al., 2013; Kubo et al., 2011; Putz et al., 2014) and rare-earth ions, especially erbium (Afzelius et al., 2013; Bushev et al., 2011; Probst et al., 2013; Staudt et al., 2012). An entirely different approach that has shown promise is to use optomechanical systems, where mechanical vibrations (phonons) in nano- or micro-mechanical systems act as an intermediary between the microwave and optical photons (Andrews et al., 2014; Bochmann et al., 2013; Lin et al., 2010). Finally, collective magnon excitations in macroscopic ferrimagnetic crystals are also being studied as a potential medium for an interface (Tabuchi et al., 2014). The shear range of physical systems being studied as a potential implementation of a quantum interface speaks to the compelling nature of the problem.

III. MULTIPLE EMITTERS IN THE STRONG-COUPLING REGIME

Investigating the interaction of propagating photons with multiple emitters in 1D continuum, as illustrated in Fig. 13 (Color online), is of fundamental and practical importance. For example, photon-mediated interaction between distant emitters, as recently demonstrated in 1D (Lalumiére et al., 2013; van Loo et al., 2013), can be used to generate long-range entanglement between the emitters (Gonzalez-Tudela et al., 2011; Greenberg and Shtygal, 2015; Zheng and Baranger, 2013). More generally, we can imagine systems with multiple emitters being used in increasingly more advanced quantum communication nodes. Moreover, strong coupling of multiple emitters with propagating photons confined below the diffraction limit has potential practical applications for detection and subwavelength imaging of atoms, ions, molecules, QDs, or color centers in a host crystal (Bushev et al., 2011; Chen et al., 2010; Kühn et al., 2006; Rezus et al., 2012; Roy, 2013a; Smolyaninov et al., 2005). Finally, systems of multiple emitters may realize photonic simulators for the quantum many-body dynamics of electrons in condensed matter. Examples of analyzed phenomena in such simulators include a Luttinger liquid of photons (Angelakis et al., 2011), quantum phase transitions of light (Greentree et al., 2006; Hartmann et al., 2006), optical Josephson interferometry (Gerace et al., 2009), and the Tonks-Girardeau gas of photons (Chang et al., 2008).

The potential of multi-emitter systems has motivated a number of theoretical studies in recent years. While most have been within the standard Markovian approximation (Caneva et al., 2015; Chang et al., 2012; Dzsotjan et al., 2010; Roy, 2013a; Yudson and Reineker, 2008), others have looked for distinctly non-Markovian effects (Laaksö and Pletyukhov, 2014; Zheng and Baranger, 2013).

A. Photon-mediated interaction between distant emitters

The interaction of an isolated emitter with the vacuum fluctuations of the electromagnetic field leads to the spontaneous emission of real photons and to a renormalization of its transition frequency (Lamb shift) via the emission and absorption of virtual photons. A second emitter in the system can absorb both types of these photons, giving rise to an effective interaction between the two emitters (Goldstein and Mestres, 1997). In a 3D space, the strength of such interaction falls off rapidly with the separation between the emitters because of the large mode volume of the photons and the resulting mode mismatch with the emitters. (DeVoe and Brewer, 1996; Eschner et al., 2001). As we saw for single emitters, these limitations are mitigated by confining the system to 1D.

Recently, the Zürich group observed clear signatures of photon-mediated interaction between two superconducting transmon qubits (van Loo et al., 2013). The physical separation between the emitters was large enough that there was no direct coupling between them. While the actual separation $d = 18.6 \text{ mm}$ was fixed in the experiment, the normalized separation $d/\lambda$, measured in transition wavelengths, was changed by tuning the transition frequency of the emitter. The normalized separation could be tuned between $d/\lambda = 1$ and $d/\lambda = 3/4$.

For $d/\lambda = 1$, the two emitters are driven with the same
amplitude and phase by any resonant field in the transmission line. This led to the observation of a superradiant bright state and a subradiant dark state. For $d/\lambda \sim 3/4$, one emitter is at a node of the propagating field when the other is at an antinode, suppressing these superradiant effects. However, an exchange interaction mediated by virtual photons is maximized. The anticrossing in the two qubit spectrum caused by this exchange interaction was observed in the resonance fluorescence spectrum of the driven two-emitter system, as shown in Fig. 14. Laflumière et al. (2013) described the two-emitter system of the Zurich group using a Markovian master equation along with input-output theory (Lehmberg, 1970), obtaining good agreement with the experimental results.

We note that the coherent exchange mediated by photons can generate a high degree of long-distance entanglement between the emitters (Dzsotjan et al., 2010) Fang and Baranger, 2015; Fang et al., 2014; Gonzalez-Tudela et al., 2011; Hensen et al., 2015 which is an important ingredient for quantum information science.

B. Small ensemble of adjacent emitters

Several studies have been carried out on small ensembles of adjacent emitters with no intrinsic interaction. (We consider intrinsic interactions in Sec. IV Rephaeli et al., 2011) calculate 2-photon scattering from a pair of adjacent 2LEs, predicting that the fluorescence of the emitters is completely quenched for a proper choice of input (Zhou and Swain, 1996). Roy (2013b) compared 1-photon and 2-photon scattering from two 2LEs versus a single V-type 3LE, showing that the two cases can be distinguished by the statistics of the scattered field. Zapasskii et al. (2013) successfully demonstrated this in optical spin-noise spectroscopy experiments.

C. Directional photon propagation

Strong transverse confinement of guided photons leads to large intensity gradients on the wavelength scale. In this nonparaxial regime, spin (polarization) and orbital angular momentum of light are coupled, an effect known as spin-orbit coupling. In particular, the spin state varies within the transverse plane and along the propagation direction in the waveguide. Interestingly, the local spin of this strongly confined light can be orthogonal to the propagation direction.

Utilizing the spin-orbit coupling, several experimental groups (Le Feber et al., 2015; Petersen et al., 2014) have recently demonstrated nonreciprocal scattering of light from dipolar scatterers (QDs, gold nanoparticles, alkali atoms) coupled to waveguides (photonic crystals, nanofibers). The propagation direction of scattered light in such systems depends on the spin direction of the incident light. Control of the directionality of the scattering process with over 90% efficiency has been achieved in such nanophotonic waveguide interfaces. Mitsch et al. (2014) have further shown directional spontaneous emission of photons from emitters into a nanophotonic waveguide. Bliokh et al. (2015) argue that the transverse spin in evanescent waves and the spin-controlled directional excitation of surface or waveguide modes is analogous to the quantum spin Hall effect.

Directional propagation due to collective scattering, distinct from the above effects, was theoretically studied by Roy (2010a, 2013a) in spatially asymmetric atom-waveguide interfaces. Two different structures were investigated using scattering theory: a 2LE directly coupled to two waveguides with different coupling strengths, and a chain of closely spaced 2LEs with varying transition frequencies (Fratini et al., 2014) along the chain. While the 1-photon transmission is reciprocal in these systems, the two or multiphoton transmission is nonreciprocal due to the broken spatial symmetry. These systems can thus act as optical diodes or isolators (Jalas et al., 2013) for few photon states.

IV. MULTIPLE INTERACTING EMITTERS IN THE WEAK-COUPLING REGIME: RYDBERG POLARITONS

Up until this point, we have considered explicitly only the interaction between photons arising from their coupling to the same emitter. In these configurations, efficient interaction requires the strong-coupling condition $\Gamma/\gamma \gg 1$, where the coupling $\Gamma$ of the emitter to the confined probe channel is faster than all other relaxation rates $\gamma$, including spontaneous emission to the vacuum environment. In the alternative approach we shall now discuss, the interaction between photons is obtained without mode confinement in the opposite regime of weak coupling $\Gamma/\gamma \ll 1$, by utilizing many atoms, which in...
FIG. 15 (Color online). (a) Schematics of a typical Rydberg-polaritons setup: a cloud of ultracold alkali atoms is held between two confocal lenses. The outgoing probe photons are measured using single-photon detectors. (b) Normalized second-order correlation $g^{(2)}$ of the outgoing probe versus the time separation $\tau$ between the photons, showing the transition from antibunching in the dissipative regime ($\Delta = 0$) to bunching in the dispersive regime ($\Delta = 4.6\gamma$). The group delay in the medium was $0.25\ \mu s$. Points are experimental data, lines are numerical simulations. (c) Conditional phase-shift obtained from a tomographic reconstruction of the outgoing 2-photon wavefunction. (d) Signature of the 2-photon bound state: The interaction potential $U(r)$ is approximated by a well of width $2r_B$ (bottom, dash-dot line). The resulting bound state, observed in the shape of the measured $g^{(2)}$ (top, circles, where time is converted to distance via $x_2 - x_1 = \tau v_{\text{ETT}}$), conforms to that calculated using Eq. (43) (top, solid line). The initial state $\psi(r,0) = 1$ (bottom, dashed line) is a superposition of the bound state (bottom, thick line) and the manifold of scattering states (bottom, thin line). Adapted from Peyronel et al. (2012) and Firstenberg et al. (2013).

turn are intrinsically interacting.

In free space, the cumulative effect of $N$ atoms is often characterized by the resonant optical depth $\text{OD} = 2N\tau/(\gamma + \Gamma) = N\sigma_a/A$ (Caneva et al. 2015). The atomic cross-section $\sigma_a$ is at most $\sim \lambda^2$ and typically much smaller than the focused beam area $A$, hence high OD are obtained only for large $N$. Taking $t_k$ from Eq. (13), we recover a well-known expression for the total transmission amplitude $t_k^N = \exp(-\text{OD}/2)\Delta + \gamma$ at $\Gamma/\gamma \ll 1$, where $\Delta$ is the detuning of the light from resonance. However contrary to the strong-coupling case, here most of the non-transmitted light is lost rather than reflected. The ratio between the single-atom reflection coefficient $|r_k|^2$ from Eq. (13) and the loss $1 - |r_k|^2$ is $\Gamma/(2\gamma) \ll 1$. Furthermore as we have seen, strong coupling is required for obtaining significant photon-photon correlation (cf. Fig. 7). Indeed while high OD is useful for observing and utilizing single-photon effects, two more ingredients, namely the cooperative behavior of the atoms and suppression of loss, are required for strong photon-photon interactions in the weak-coupling regime.

Rydberg atoms provide such cooperativity via the dipole blockade mechanism (Lukin et al. 2001). When exciting two or more atoms to Rydberg states — electronic states with a large principal quantum number $n$ (typically $n = 40$ to $100$) — the dipolar interaction between them shifts their Rydberg levels and consequently their excitation frequency (Reinhard et al. 2007). Below a certain distance between the atoms, known as the blockade radius $r_B$ (typically $\leq 10\ \mu m$), the frequency shift is larger than the excitation linewidth (typically $1 - 10\ \text{MHz}$ for cold atoms), blocking the excitation of more than one atom. Such large $r_B$ are achieved at the van-der-Waals regime, where the frequency shift depends on the extremely large dipoles ($\sim 10^4\ \text{Debye}$) to the power of 4. The blockade effect itself can be used for various quantum information processes with atoms (Müller et al. 2009; Saffman et al. 2010).

The consequence of the dipole blockade for propagating photons in quite intuitively understood. A single photon, exciting a single Rydberg atom, can block the excitation of all $N_B \gg 1$ atoms in the surrounding virtual sphere of radius $r_B$. If the optical depth of the blockade sphere OD$_B = N_B\sigma_a/A$ is large, it allows a single photon to significantly alter the optical response for other photons.

The final ingredient required for effective photon-photon interactions in the weak-coupling limit is the suppression of loss, which can be accomplished using EIT as proposed by Friedler et al. (2005). A ladder-type configuration as in Fig. 8(b) is used, with a probe photon exciting the ground-state atom to an intermediate state, which is coupled to the Rydberg state by a strong control field with Rabi frequency $\Omega_c$. The probe is transmitted due to EIT within a narrow spectral window. By shifting this window, the dipole blockade disables the EIT for more than one probe photon in the blockade sphere. A strong dependence on the rate of incoming probe photons can be observed by monitoring the average transmission (Pritchard et al. 2013). The optical nonlinear behavior and the emergence of non-classical correlations during propagation were theoretically investigated within the mean-field approximation by Pritchard et al. (2010), Sevinçli et al. (2011), Petrosyan et al. (2011), and others.

The transmitted probe experiences strong dispersion and thus reduced group velocity $v_{\text{ETT}} \ll c$, where $c$ is the speed of light in vacuum. It is therefore instructive to
view each propagating photon as a slow light-matter polariton [Fleischhauer and Lukin 2000]. Typically these polaritons have a negligible photonic component, of order $v_{\text{EIT}}/c$, guaranteeing the excitation of a Rydberg atom per each propagating photon at any given time. The strong dipolar forces between two Rydberg atoms thus effectively mediate interaction between the two propagating photons.

### A. Two-photon dynamics

Gorshkov et al. (2011) provide a quantum description for two photons, which we now follow. A probe photon in the form of a polariton blocks EIT for the second probe photon, which experiences the response $\mu_k^{g} = \exp(-\frac{OD_B}{L} \Delta)$ of bare two-level atoms. The nature of the photon-photon interaction is thus controlled by the detuning of the probe $\Delta$ from the intermediate atomic state. On-resonance excitation ($\Delta = 0$) leads to scattering of the second photon, inducing an effective dissipative interaction between the photons. The second photon is scattered inside the blockade sphere with a probability $1 - e^{-OD_B}$. In contrast, for off-resonance excitation ($|\Delta| \gg \gamma$), the second photon experiences much less scattering but acquires a nonzero phase $\phi = -(\gamma/\Delta)OD_B/2$. This leads to a conditional phase shift $\phi$ for two or more photons, inducing a dispersive interaction between the photons. We see that for both on and off resonant processes, OD$_B$ is the key parameter determining the strength of the effective interaction.

Nonlinear optical response with Rydberg polaritons was demonstrated originally with OD$_B \ll 1$ by Pritchard et al. (2010). The limit of quantum nonlinearity was afterwards reached with OD$_B \approx 10$ by Peyronel et al. (2012) in a system illustrated in Fig. 15(a). The long axis of an elongated cloud of ultra-cold atoms was $L \approx 100 \mu$m, and so naively could fit 10 blockade spheres of radius $r_B \approx 10 \mu$m, each containing $N_B \approx 1000$ atoms. To render an effective 1D system, the light was focused to a diameter larger than the wavelength but smaller than $r_B$. In this way, paraxial diffraction did not substantially alter the transverse extent of the photon wavefunction along its propagation, and at the same time, two polaritons propagating side-by-side blocked each other.

Quantum tomography can be used to completely characterize the outgoing 2-photon state as a function of the time separation $\tau$ between the photons (Firstenberg et al. 2013). In particular, it yields the second-order correlation function $g^{(2)}(\tau)$ and the conditional phase-shift $\phi(\tau)$ relative to the noninteracting case.

The dissipative interaction at $\Delta = 0$ was observed by Peyronel et al. (2012) at an average level of less than one photon in the medium. The probability that two photons exit the medium simultaneously was suppressed by the blockade mechanism, resulting in photon antibunching $g^{(2)}(0) < 1$, as seen in Fig. 15(b). The dispersive interaction at $\Delta \neq 0$ was demonstrated by Firstenberg et al. (2013). In addition to a large conditional phase shift $\phi(0) = 45^\circ$ [Fig. 15(c)], photon bunching $g^{(2)}(0) > 0$ was observed [Fig. 15(b)].

The bunching in the dispersive regime can be attributed to an effective attractive force between the photons, intuitively arising from an increase in the group velocity inside the blockade volume. To better describe the 2-photon dynamics, one defines an effective 2-photon wavefunction inside a medium of length $L$ as a function of the coordinates $x_1$ and $x_2$ of the two photons

$$\psi(x_1, x_2) = \frac{\langle \varphi | a(x_1)a(x_2) | \Psi \rangle}{\langle \varphi | a(x_1) | \Psi \rangle \langle \varphi | a(x_2) | \Psi \rangle}.$$ (42)

Here $|\Psi\rangle$ is the full wavefunction of the system and $a(x)$ annihilates a photon at position $x$. We assume a stationary scenario with a constant incoming coherent state. Due to symmetry, it is useful to work with the relative $r = x_2 - x_1$ and mean $R = (x_1 + x_2)/2$ coordinates. From the definition (42), classical light in the absence of photon-photon interactions is described by $\psi(r, R) = 1$; complete photon blockade corresponds to $\psi(0, L) = 0$, which is measured in experiments using $|\psi(0, L)|^2 = g^{(2)}(0)$; and a pure conditional phase $\phi$ corresponds to $\psi(0, L) = e^{i\phi}$.

Firstenberg et al. (2013) show for $\Omega_c \ll \Delta$ that $\psi(r, R)$ approximately follows a Schrödinger-like equation with $R$ playing the role of time,

$$i \frac{\partial \psi}{\partial R} = 4\frac{\mu_\alpha^2}{\gamma} \frac{\partial^2 \psi}{\partial r^2} + \frac{\gamma}{l_\alpha^2}U(r)\psi.$$ (43)

Here $l_\alpha = L/OD_B = 2r_B/OD_B$ is the attenuation length. Assuming a repulsive van-der-Waals interaction, the effective potential can be approximated by the step function $U(|r| \leq r_B) = 1$. The effective photon mass of this Schrödinger-like evolution originates from the quadratic component ($\propto k^2$) of the dispersion of individual polaritons. This component causes the change in group velocity when the Rydberg level shifts.

Equation (43) approximately describes a potential well. Both the mass and the potential terms flip signs for $\Delta \rightarrow -\Delta$, so the effective force remains attractive. The 2-photon bound state of the finite-well potential, shown in Fig. 15(d), governs the evolution of an incoming wavefunction $\psi(r, 0) = 1$. In Fig. 15(d), in order to compare the measured $g^{(2)}(\tau)$ to the calculated $\psi(r, L)$, the time $\tau$ has been converted to distance $r$ using the group velocity $v_{\text{EIT}} = l_\alpha \Omega_c^2/(2\gamma)$. In experiments, $\Omega_c^2 \ll c^2/l_\alpha^2$ and thus $v_{\text{EIT}} \ll c$, as we have assumed throughout this section. Following this initial model, Bienias et al. (2014) have used scattering theory to study the 1D scattering properties for two photons for a wide range of the system parameters. By calculating the effective 1D scattering length, they predict the existence of scattering resonances analogous to Feshbach resonances in cold atoms, where...
the interaction turns from attractive to repulsive. For the experimental parameter regime described above, Br-enias et al. (2014) generalize Eq. (43) to account for non-stationary (but slowly-varying) probe input, essentially replacing the term \( \partial/\partial R \) by \( \partial/\partial R + \partial/(v_{\text{EIT}} \partial t) \).

Lately, two more treatments for the system have been introduced. Caneva et al. (2015) model the atomic ensemble by a chain of 3LEs along a 1D waveguide, generalizing the input-output formalism presented in the previous sections. With this effective description, they recover the mean ensemble behavior (e.g., the optical depth and \( v_{\text{EIT}} \)) and provide a recipe for calculating the high-order correlations of the outgoing photons. In parallel, Moos et al. (2015) write down an exact many-body model for the system, including the loss (scattering out of the system) and the paraxial propagation of the probe light, and provide the conditions under which the model is reduced to an effective many-body system of slow-light polaritons in 1D. They verify the model in the 2-photon case by comparing it to exact numerical simulations.

B. Many photons

Recently, two groups have demonstrated storage of Rydberg polaritons for implementing a single-photon switch or transistor (Baur et al. 2014, Gorniaczyk et al. 2014, Tiarks et al. 2014). In these experiments, a ‘gate’ Rydberg polariton is first converted into a stationary excitation (a spin wave) of one Rydberg atom by turning off the control field. Subsequent ‘signal’ polaritons, coupled to a different Rydberg state, are blocked by the stored polariton. The number of signal photons gated by the stored excitation determines the ‘gain’ of the transistor, recently reaching 100 (Gorniaczyk et al. 2016).

So far, the many-body behavior of Rydberg polaritons has been limited to theoretical studies. Zeuthen et al. (2016) describe the many-body evolution in the dissipative regime, where the system can act to transform a classical input to a regular train of single photons. Bienias et al. (2014) formulated a low-energy many-body Hamiltonian in the dispersive regime based on their derivation of the 1D scattering length. Otterbach et al. (2013) introduced an approximate Hamiltonian and used Luttinger liquid theory to predict the Wigner crystallization of Rydberg polaritons. To this end, they assumed an initial transient (preparation) phase where co-located polaritons are scattered out of the system, such that the photon-particle interaction is dominated by the tail of the repulsive van-der-Waals interaction. Moos et al. (2015) followed up on these arguments to derive their aforementioned effective many-body model and used numerical calculations (with the DMRG method) to compare with the Luttinger liquid result.

C. Limitations and prospects

In a long medium \( (L > 2r_B) \), a co-propagating pair of interacting photons traverses several blockade radii. The accumulated effect of the interaction can be calculated from Eq. (43) or from its generalization to the dissipative regime. Such calculations take into account the distortion (dispersion and absorption) of the photon wave-packet due to the finite bandwidth of the EIT transmission window, manifested in Eq. (43) by the mass term. The results depend on both OD and OD_B, with dissipative interaction \( \Delta = 0 \) yielding a blockade probability \( 1 - OD^{-1/2}e^{-OD_B} \) (Peyronel et al. 2012) and dispersive interaction \( \Delta \gg e \) yielding a conditional phase shift \( \phi \propto \sqrt{OD \times OD_B} \) (Firstenberg et al. 2013).

Nevertheless, while OD strengthen the overall effect as implied by the above expressions, it is now widely accepted that OD_B \( \gg 1 \) alone is the key condition for high fidelity of quantum-information operations. Under this condition, the optimized arrangement is a medium completely residing within one blockade volume \( (L \leq 2r_B) \) and thus OD = OD_B \( \gg 1 \). Intuitively in the co-propagating case, this arrangement guarantees that the wave-packets of both photons are fully contained within the interaction range \( (r_B) \), so that the fidelity is not reduced by partial entanglement of different parts of the wave-packets. In the case of the aforementioned photonic switch, the gating probability of a ‘signal’ polariton by a stored ‘gate’ polariton equals \( 1 - e^{-OD_B} \) and the decoherence of the ‘gate’ during the operation scales as \( e^{-OD_B} \) (Li and Lesanovsky 2015; Murray et al. 2016); the overall infidelity of the switch is thus governed by the inefficiency of storage and retrieval of the ‘gate’, scaling unfavorably as \( 1/OD_B = 1/OD \) (Gorshkov et al. 2007). For realizing strongly-correlated many-body states of co-propagating photons, such as the photon train or the Wigner crystal, the requirements on OD_B become even more stringent (Otterbach et al. 2013, Zeuthen et al. 2016).

So far, experiments have reached OD = OD_B = 13 (Tresp et al. 2016). When using a single Rydberg level, Gaj et al. (2014) and Baur et al. (2014) predicted a limit OD_B \( \lesssim 20 \) due to formation of Rydberg molecules at high atomic densities. A particularly promising approach to circumvent this limit is by tuning so-called Förster resonances between two different Rydberg levels (Gorniaczyk et al. 2016, Tiarks et al. 2014). Another approach is the introduction of an optical cavity with a finesse \( F \) around the atomic ensemble, where the condition OD_B \( \gg 1 \) is replaced by \( FOD_B \gg 1 \) (Das et al. 2016). Such enhancement of the coupling was first demonstrated by Parigi et al. (2012), and recently long-lived cavity-Rydberg polaritons were realized (Ningyuan et al. 2016).
V. CONCLUSIONS AND PERSPECTIVES

Advances in both quantum optics and classical nonlinear optics were fueled by developments in laser, material, and electronic technologies, but apart from occasional intersections, these two fields remained almost separated for half a century. Research was mostly limited to the study of either high-intensity fields with macroscopic or mesoscopic materials or low-intensity fields with individual atoms. It is the recent development in realizing and understanding effective strong photon-photon interactions at low light intensities in various systems that triggered the new field of ‘quantum nonlinear optics’ (Chang et al. 2014).

There has been significant progress in theoretically describing nonlinear, out-of-equilibrium dynamics of scattered photons from individual emitters in a 1D continuum. A large set of all-optical quantum devices and logic, such as single-photon routers and switches, few-photon optical diodes, and conditional phase gates, has been proposed using individual two- or multi-level emitters in 1D. Some of these could find potential applications in future optical quantum circuits. However, our current understanding of light-matter interactions in the mesoscopic regime, with an ensemble of intrinsically interacting or noninteracting emitters, and the ensuing strongly-correlated dynamics, is still at its infancy. This mesoscopic quantum regime was addressed earlier in theoretical studies of quantum solitons in optical fibers (Drummond et al. 1993). Hydrodynamic, as well as microscopic descriptions, were developed to investigate strong light-matter interaction in this regime. However, the intrinsic nonequilibrium nature of the current experimental systems calls for more careful investigation to obtain a fully quantum mechanical theory in the mesoscopic regime. Numerical methods – especially time-dependent DMRG may play an important role.

The dynamics of strongly confined propagating photons interacting with multiple emitters is similar to the nonequilibrium dynamics of many-body condensed matter systems, but still shows some important differences. One significant feature of photonic systems is the controllability over their parameters, including the strength of the interactions and dissipation. This makes the photonic systems suitable candidates for performing quantum simulation of condensed matter phenomena. Nevertheless, it is also of fundamental interest to investigate quantum nonlinear dynamics in the regime where the number of particles (i.e., photons) is not conserved. This is a unique feature of photonic systems compared to natural closed material systems. In particular, it is interesting to explore the role of loss and dissipation in the quantum-to-classical transition of mesoscopic many-body systems. The interplay of spin-orbit interactions and the collective scattering of light has not been studied so far, and it is an important direction for future studies. In the presence of disorder, these nonlinear systems have the potential to exhibit many-body localization of photons, which has been very little explored theoretically or experimentally.

In a few short years, the experimental efforts with scattering of microwave photons from superconducting artificial atoms and with Rydberg polaritons in cold atomic ensembles have produced multiple interesting and important results. So far, the majority of the results with superconducting systems have involved only a single artificial atom. However, these systems are very well suited for scaling up to more atoms. The standard nanofabrication techniques employed in making the devices studied here can easily produce devices of many atoms with well-controlled spacing, coupling, detunings, etc. The range of possible experiments is diverse, ranging from exploring fundamental physics of mesoscopic atom-photon systems to more sophisticated devices for quantum nodes. In addition to increasing the system size, superconducting circuits have room to increase the atom-photon coupling strengths into new regimes that have not been explored experimental in any system. In fact, ultrastrong coupling, where $\Gamma \sim \omega_c$, has recently been demonstrated experimentally (Forn-Díaz et al. 2016; Peropadre et al. 2013; Sanchez-Burillo et al. 2014). The ultrastrong-coupling regime promises many new surprises.

At the same time, we saw that strong photon-photon interactions are also enabled in the weak-coupling regime by the action of atomic cooperativity in an ensemble. Rydberg atoms, in particular, exhibit such cooperativity via the blockade mechanism. The dipolar interaction between the Rydberg atoms conceptually transforms the blockade sphere to a two-level superatom, replacing the 2LE of the strong-coupling regime. In both regimes, the photon-photon interaction is governed by the 2-photon blockade mechanism. The dipolar interaction between the Rydberg atoms conceptually transforms the blockade sphere to a two-level superatom, replacing the 2LE of the strong-coupling regime. In both regimes, the photon-photon interaction is governed by the 2-photon blockade mechanism. The dipolar interaction between the Rydberg atoms conceptually transforms the blockade sphere to a two-level superatom, replacing the 2LE of the strong-coupling regime. In both regimes, the photon-photon interaction is governed by the 2-photon blockade mechanism. The dipolar interaction between the Rydberg atoms conceptually transforms the blockade sphere to a two-level superatom, replacing the 2LE of the strong-coupling regime.
perimental systems, further developments are soon to be implemented in the preparation of the atomic medium, the atomic excitation schemes, and the optical mode confinement. We expect the field to continue evolving alongside the single-emitter systems and predict that many of the existing ideas, and certainly more to come, will be realized in the near future.

Appendix A: Derivation of the input-output formalism

The effective Hamiltonian of a two-level emitter coupled to chiral (right-moving) photon mode in 1D continuum is given by

\[ H^R = \int_{-\infty}^{\infty} dk \; v_g k a_{R,k}^\dagger a_{R,k} + \frac{1}{2}\omega_c \sigma_z + \frac{V}{\sqrt{2\pi}} \int_{-\infty}^{\infty} dk [a_{R,k}^\dagger \sigma_- + \sigma_+ a_{R,k}] \]  \hspace{1cm} (A1)

The Heisenberg equations of motion for the operators are

\[ \frac{da_{R,k}}{dt} = -i v_g k a_{R,k} - iV \sqrt{2\pi} \sigma_- , \] \hspace{1cm} (A2)

\[ \frac{d\sigma_-}{dt} = -i \omega_c \sigma_- + iV \sqrt{2\pi} \int dk \sigma_+ a_{R,k} , \] \hspace{1cm} (A3)

\[ \frac{d\sigma_z}{dt} = 2iV \sqrt{2\pi} \int dk (a_{R,k}^\dagger \sigma_- - \sigma_+ a_{R,k}) . \] \hspace{1cm} (A4)

Equation \[ \text{(A2)} \] is formally solved by multiplying it by \( e^{iv_g k t} \) and integrating from an initial time \( t_0 \) to get

\[ a_{R,k}(t) = a_{R,k}(t_0) e^{-i v_g k (t-t_0)} - iV \sqrt{2\pi} \int_{t_0}^{t} dt' \sigma_- (t') e^{iv_g k (t'-t)} \] \hspace{1cm} (A5)

Next we integrate Eq. \[ \text{(A5)} \] with respect to \( k \) and introduce a field operator

\[ \Phi(t) = b_{R,in}(t) - iV \frac{\sigma_-}{2v_g}(t) , \] \hspace{1cm} (A6)

where \( \Phi(t) = (1/\sqrt{2\pi}) \int dk a_{R,k}(t) \), and an input operator \[ \text{Fan et al., 2010} \]

\[ b_{R,in}(t) = \frac{1}{\sqrt{2\pi}} \int dk a_{R,k}(t_0) e^{-iv_g k (t-t_0)} . \] \hspace{1cm} (A7)

Plugging Eq. \[ \text{(A6)} \] in Eqs. \[ \text{(A3)} \] and \[ \text{(A4)} \], we get

\[ \frac{d\sigma_-}{dt} = iV \sigma_z b_{R,in}(t) - \frac{1}{2} \sigma_- - i\omega_c \sigma_- , \] \hspace{1cm} (A8)

\[ \frac{dN_{e}}{dt} = -iV (\sigma_+ b_{R,in}(t) - b_{R,in}(t)^\dagger \sigma_-) - \Gamma N_{e} , \] \hspace{1cm} (A9)

where \( \Gamma = V^2/v_g \) and \( N_{e} = (\sigma_z + 1)/2 \). Similarly by integrating Eq. \[ \text{(A2)} \] up to a final time \( t_1 > t \), we find

\[ \Phi(t) = b_{R,\text{out}}(t) + iV \frac{\sigma_-}{2v_g}(t) . \] \hspace{1cm} (A10)

Finally we can write from Eqs. \[ \text{(A6)} \] and \[ \text{(A10)} \]

\[ b_{R,\text{out}}(t) = b_{R,in}(t) - iV v_g \sigma_-(t) . \] \hspace{1cm} (A11)
