Summary We previously reported that low-dose X-irradiation alleviates ischemia-reperfusion injury such as mouse paw edema. In this study, we examined active changes in the biological function of mouse liver grafts in cold storage after low-dose X-irradiation. Mouse livers were sham-irradiated or were irradiated with 0.25, 0.5, 1.0, or 5.0 Gy of X-ray and stored for 4, 8, 24, or 48 h in preservation or saline solution. The results show that storage for 24 h in saline solution after 0.5 Gy irradiation significantly increased the activity of superoxide dismutase (SOD) and catalase. Following storage for 4, 8, or 48 h in preservation solution, lipid peroxide levels of the 0.5 Gy irradiated group were significantly lower than those of the sham irradiated group. Following storage for 24 h in preservation solution, the activity of SOD and catalase of the 1.0 Gy irradiated group were significantly higher than those of the sham irradiated group. Hepatocytes stored in saline solution were vacuolated. However, no vacuole formation was observed in hepatocytes stored in preservation solution. These findings suggest that low-dose irradiation significantly activates antioxidative functions of liver grafts. Moreover, the dose at which enhancement of antioxidative function occurs in livers stored in preservation solution, which contains glutathione, is significantly higher than that in saline solution.

Key Words: organ transplantation, low-dose irradiation, antioxidative function, hepatopathy

Introduction

Clinical liver transplant is now widely applied for the treatment of end-stage liver disease. About 11,000 transplants are done annually worldwide. Patient survival at one year and five years is 85–90% and 75–80%, and graft survival is 80–85% and 70–75%, respectively [1]. Ischemia-reperfusion injury is an inevitable result of liver transplantation and is closely related to the development of primary graft non-function and primary graft dysfunction [2]. Both conditions are associated with high rates of morbidity and mortality. In addition, ischemia-reperfusion injury increases the incidence of subsequent graft rejection [3]. Livers are stored in a cold (4°C) solution, such as Collins’ solution or University of Wisconsin (UW) solution until transplantation. Canine livers are stored in UW solution for 24, 30, 36, or 48 h and transplanted animals that survive beyond 5 days after transplantation have excellent graft functions [4].

It is well known that ischemia-reperfusion injury is attributable to reactive oxygen species (ROS). Transient hypoxia increases hypoxanthine and xanthine in cells. The superoxide radical generated by xanthine oxidase (XOD) contributes to the development of ischemia-reperfusion injury [5, 6], and treatment with superoxide dismutase (SOD) shows beneficial effects on rat graft liver [7]. These results indicate that SOD plays an important role in the inhibition of ischemia-reperfusion injury after liver transplantation.

Low-dose irradiation increases endogenous antioxidants
in animal tissue. It has been reported that antioxidants such as SOD [8–11], glutathione peroxidase (GPx) [9, 11], glutathione reductase (GR) [12], glutathione [11, 12], catalase [11], and thioredoxin [11] are activated and/or induced by low-dose irradiation and that they contribute to the inhibition of oxidative injury. Furthermore, we previously reported inhibitory effects of prior low-dose X-irradiation on ischemia-reperfusion injury in mouse paw [13]. These findings suggested that low-dose irradiation enhances antioxidative function and alleviates ischemia-reperfusion injury. Most of these studies have reported that activation of antioxidative function is induced by cell or whole body irradiation. Activation of antioxidative function in grafts could potentially inhibit ischemia-reperfusion injury after transplantation. However, there have been no reports of changes in the antioxidative function of grafts following low-dose irradiation after exenteration. In the present study, we examined changes in antioxidative function and hepatocyte histology induced in extirpated mouse liver by low-dose X-irradiation. Antioxidative functions such as lipid peroxide levels, total glutathione content, the activity of SOD and catalase were investigated as well as histological changes in the livers under various conditions of irradiation and storage.

Materials and Methods

Animals, liver irradiation and storage

Male BALB/c mice (body weight of about 25 g, age; seven to eight weeks) were kept in an air-conditioned room (temperature: 20°C, humidity, 60%) at the Department of Animal Resources, the Advanced Science Research Center, Okayama University. Livers were perfused with a physiological saline solution under ether anesthesia before the livers were harvested and stored for 4, 8, 24, or 48 h in preservation solution (Via Span; Bristol-Myers Squibb Co.), at 4°C or in physiological saline solution (saline solution, pH 7.8 at 4°C). The preservation solution was used as a model for UW solution. Prior to storage in these solutions, the extirpated livers were irradiated at a dose of 0.25, 0.5, 1.0, or 5.0 Gy (3.0 Gy/min) using an X-ray generator (Hitachi MBR-1505R2, voltage; 150 kV, amper; 20 mA, filters; Cu:Al = 0.5 mm:0.2 mm) at room temperature. The livers were stored in the solutions immediately after irradiation. At the end of this period of storage, livers were preserved at −80°C until biochemical assay. Liver sections were fixed in 10% neutral-buffered formalin for histological observation. For comparison, the livers of a control group were sham irradiated immediately after liver exenteration and stored at −80°C until biochemical assay. The study protocol was in accordance with the animal experimental guidelines of Okayama University.

Biochemical assays

Lipid peroxide (malondialdehyde (MDA)) levels were assayed using Bioxytech LPO-586™ assay kit (OXIS Health Products, Inc., OR). Briefly, livers were homogenized in 20 mM phosphate buffer (PBS; pH 7.4) on ice. Prior to homogenization, 10 µL of 0.5 M butylated hydroxytoluene in acetonitrile were added per 1 mL of tissue homogenate. After homogenization, the homogenate was centrifuged at 15,000 × g for 10 min at 4°C and the supernatant was used for assay. The MDA assay is based on the reaction of a chromogenic reagent, N-methyl-2-phenylidole, with MDA at 45°C. The optical density of the colored products was read at 586 nm in a spectrophotometer. The protein content was measured by the Bradford method, using Protein Quantification Kit-Rapid (Dojindo Molecular Technologies, Inc., Kumamoto, Japan).

Total glutathione content was measured using the Bioxytech GSH-420™ assay kit (OXIS Health Products). Briefly, livers were suspended in 10 mM phosphate buffer (pH 7.4), mixed with ice-cold 7.5% trichloroacetic acid solution and then homogenized. The homogenates were centrifuged at 3,000 × g for 10 min. The supernatant was used for the assay. Total glutathione content was measured at 420 nm using a spectrophotometer. This assay is based on the formation of a chromophoric thione the absorbance of which, measured at 420 nm, is directly proportional to the total glutathione concentration.

Mouse liver was homogenized in a 1 M Tris-HCl buffer containing 5 mM ethylendiaminetetraacetic acid (EDTA) (pH 7.4) on ice. The homogenate was centrifuged at 15,000 × g for 45 min at 4°C and the supernatant was used for assay of the activity of SOD and catalase.

SOD activity was measured by the nitroblue tetrazolium (NBT) reduction method [15] using the Wako-SOD test (Wako Pure Chemical Industry, Co., Ltd., Osaka, Japan). Briefly, the extent of inhibition of the reduction in NBT was measured at 560 nm using a spectrophotometer. One unit of enzyme activity was defined as 50% inhibition of NBT reduction.

Catalase activity was measured as the hydrogen peroxide (H₂O₂) reduction rate at 37°C and was assayed at 240 nm using a spectrophotometer [16]. The assay mixture consisted of 50 µl of 1 M Tris-HCl buffer containing 5 mM EDTA (pH 7.4), 900 µl of 10 mM H₂O₂, 30 µl deionized water, and 20 µl liver supernatant. Activity was calculated using a molar extinction coefficient of 7.1 × 10⁻³ M⁻¹cm⁻¹. Catalase activity was measured by the amount of hydrogen peroxide split by catalase in 20, 40, or 60 s at 37°C. The reactions were started by addition of the liver supernatant.

Histological observation

Livers were fixed in 10% formalin, processed with a graded mixture of ethanol and xylene and embedded in
paraffin. The 6-µm thick tissue sections were prepared and stained with hematoxylin-eosin (HE).

Statistical analyses
The data values are presented as the mean ± standard error of the mean (SEM). The statistical significance of differences was determined by Student’s t test for comparison between two groups and Dunnet’s tests for multiple comparisons where appropriate. Each experimental group consisted of 5–10 samples.

Results
Changes in the level of oxidative damage in mouse livers after irradiation
To determine changes in oxidative damage in mouse livers after irradiation various parameters of oxidative damage were assayed in livers that were stored in physiological saline or preservation solution following sham- or X-irradiation. Lipid peroxide levels were significantly increased in mouse livers kept in cold storage for 48 h in preservation solution after 0.5 Gy irradiation. Lipid peroxide levels of mouse livers kept in cold storage for 8 h in saline solution, or for 4, 8, or 48 h in preservation solution, after 0.5 Gy irradiation were significantly lower than those after sham irradiation (Fig. 1).

The total glutathione content of mouse livers kept in cold storage for 4, 8, 24, or 48 h in physiological saline or in preservation solution after sham or 0.5 Gy irradiation was significantly decreased. Total glutathione content of mouse livers kept in cold storage for 48 h in preservation solution after 0.5 Gy irradiation were significantly lower than those after sham irradiation (Fig. 2).

SOD activity of mouse livers kept in cold storage for 8, 24, or 48 h in saline solution after 0.5 Gy irradiation was significantly increased. The SOD activity of mouse livers kept for 24 h in cold storage in saline solution after 0.5 Gy irradiation was significantly decreased compared to livers kept in physiological saline solution.

Fig. 1. Changes in lipid peroxide levels of mouse livers in preservation after 0.5 Gy irradiation. Mouse livers were preserved in physiological saline or preservation solution for the indicated number of hours following sham irradiation or irradiation of 0.5 Gy as indicated. Lipid peroxide levels were measured with a commercial assay kit. Each value indicates the mean ± SEM. The number of mouse livers per experimental point is 5–10. *p<0.05, **p<0.1, ***p<0.001 vs control, *p<0.05, **p<0.1, ***p<0.001 vs sham irradiation (storage in physiological saline solution).

Fig. 2. Changes in total glutathione content of mouse livers in preservation after 0.5 Gy irradiation. Mouse livers were treated as described for Fig. 1 and glutathione content was measured by a spectrophotometric assay. The data, number of mouse livers and significance are as described for Fig. 1.
irradiation were significantly higher than those after sham irradiation (Fig. 3).

Catalase activity of mouse livers kept in cold storage for 4 or 24 h in saline solution after 0.5 Gy irradiation was significantly increased. The catalase activities of mouse livers kept for 24 h in cold storage in saline solution after 0.5 Gy irradiation were significantly higher than those after sham irradiation (Fig. 4). These data indicate that parameters of oxidation in mouse livers are highly responsive to irradiation and storage conditions.

Changes in oxidative damage levels in mouse livers kept in cold storage for 24 h after irradiation

We next examined in further detail the effect of storage of livers in preservation or saline solution for 24 h following irradiation on parameters of oxidative damage. The lipid peroxide level of mouse livers stored in preservation solution after 0.25 Gy irradiation was significantly lower than that after sham irradiation. The levels of lipid peroxide in livers kept in preservation solution after sham irradiation were significantly higher than those kept in saline solution (Fig. 5A).

The total glutathione content of mouse livers stored in preservation solution after sham, 0.5, or 1.0 Gy irradiation was significantly lower than that in saline solution (Fig. 5B).

The SOD activity of mouse livers stored in preservation solution after 0.25, 1.0, or 5.0 Gy irradiation, or in saline solution after 0.25, 0.5, or 5.0 Gy irradiation, was significantly higher than that after sham irradiation. SOD activity in livers stored in preservation solution after 1.0 Gy irradiation was significantly higher than that in saline solution (Fig. 5C).

The catalase activity of mouse livers, stored in preservation solution after 1.0 Gy irradiation, or in saline solution after 0.25 or 0.5 Gy irradiation, was significantly higher than that after sham irradiation. Catalase activity of mouse livers stored in preservation solution after 1.0 Gy irradiation was significantly higher than that in saline solution. Moreover, catalase activity in livers stored in preservation solution after sham, 0.25, or 0.5 Gy irradiation was significantly lower than that in saline solution (Fig. 5D).

These data suggest that the type of solution in which livers
Changes in Liver Graft After Low-dose Irradiation

Vol. 45, No. 2, 2009

are stored plays a critical role in the level of oxidative damage in livers during storage following irradiation.

**Histological examination**

Histological changes in mouse livers following irradiation and storage in saline or preservation solution were examined. Histological examination of hepatocytes kept in cold storage in saline solution following irradiation indicated that the hepatocytes were vacuolated under these conditions. In contrast, no vacuole formation was observed in hepatocytes kept in cold storage in preservation solution following irradiation (Fig. 6).

**Discussion**

The findings of this study provide important insights concerning oxidative changes in liver following preservation in different solutions after irradiation. Oxidative changes appear to play a critical role in ischemic injury.

The fact that SOD and catalase are just as effective as antioxidants when administered just before re-oxygenation as when administered before anoxia confirms that ischemic injury occurs primarily at re-oxygenation, and that this injury is mediated by a process dependent upon superoxide formation. Allopurinol, which inhibits xanthine oxidase synthesis, substantially reduces ischemic injury because xanthine is major source of free radical generation within endothelial cells at reoxygenation [17]. The preservation solution contains glutathione, allopurinol, and adenosine that have been added to alleviate ischemia-reperfusion injury after transplantation.

Low-dose irradiation promotes a small induction of ROS in vivo and induces the production of antioxidant substances including SOD, catalase and glutathione, in various organs [18]. Previous studies have shown that low-dose X-irradiation or low-level radon inhalation enhances antioxidative and immune functions and reduces oxidative damage such as ischemia-reperfusion injury and liver damage [13, 19–22]. In addition, it has been reported that SOD and catalase improve cell viability following ischemia-reperfusion injury after liver transplantation [23]. Thus, it is highly possible that low-dose irradiation inhibits ischemia-reperfusion injury after liver transplantation.

We examined changes in antioxidative function in liver

![Graphs showing changes in lipid peroxide level, glutathione content, and activities of SOD and catalase](image-url)

Fig. 5. Changes in (A) lipid peroxide level, (B) glutathione content, and activities of (C) SOD and (D) catalase in mouse liver preserved for 24 h following irradiation. Mouse livers were treated as described for Fig. 1 and glutathione content was measured by a spectrophotometric assay. Each value indicates the mean ± SEM. The number of mouse livers per experimental point is 5–10. *p<0.05, **p<0.01, ***p<0.001 vs each solution by sham irradiation, #p<0.05, ##p<0.01, ###p<0.001 vs physiological saline solution.
grafts following low-dose X-irradiation immediately after exenteration. Our results show that under these conditions SOD and catalase of mouse livers that are stored in saline solution after 0.5 Gy irradiation, or in preservation solution after 1.0 Gy irradiation, are significantly increased and that the peak of enhancement of antioxidative function is around 24 h after irradiation. However, a previous report suggested that the peak of enhancement of antioxidative function was around 4 h after low-dose irradiation [24]. The difference in the time of peak enhancement of antioxidative function between our study and the previous study are probably due to differences in the conditions of irradiation and preservation.

Catalase activity in mouse livers kept in cold storage for 24 h in saline solution after 0.25 or 0.5 Gy (but not 1.0 Gy) irradiation was increased compared to sham control. In
this study, we used a preservation solution which contained glutathione, allopurinol, and adenosine. Glutathione and allopurinol prevent cytotoxic injuries from oxygen free radicals. Adenosine provides a metabolic substrate for the regeneration of ATP at the initial period of reperfusion. These findings suggest that the enhancement of antioxidative function in samples that were stored in preservation solution was significantly higher than that in saline solution because a small volume of ROS, induced in vivo by excess irradiation, may be neutralized by glutathione which is contained in the preservation solution.

There was no correlation between the SOD or catalase activity and the total glutathione content. Glutathione is synthesized from L-glutamate, L-cysteine, adenine triphosphate (ATP), and glycine. However, the ATP level of liver tissue is gradually decreased during preservation in the cold [25–28]. The decline of glutathione during ischemia may reflect an inhibition of glutathione synthesis since three equivalents of ATP are required for the synthesis of one glutathione [25–28].

It is well known that peroxidation of unsaturated fatty acids of cell membrane phospholipids is accompanied by alterations in membrane structure and function. Lipid peroxidation affects the physical properties of membranes, including membrane fluidity, and normal metabolism and electron transport [29, 30]. The lipid peroxide level gradually increases during preservation of liver graft in the UW solution [31]. Our data showed that the lipid peroxide level in livers stored in preservation solution was significantly increased only at 48 h of storage. Furthermore, that there was no marked difference in lipid peroxide levels between sham and X-irradiated livers stored in physiological solution. In contrast, lipid peroxide levels of the 0.5 Gy irradiated group were lower than those of the sham irradiated group following 4, 8, or 48 h of storage in preservation solution. Previous studies have shown that low-dose X-irradiation activates antioxidant function, including the activity of SOD and catalase, and decreases the level of lipid peroxide [19, 20]. However, in this study, the activity of SOD and catalase did not appear to correlate with the prevention of lipid peroxidation either in saline solution or in preservation solution as we have previously reported [19, 20]. One activity of glutathione is the reduction of lipid peroxide. Our results showed that the total glutathione content of mouse livers maintained in cold storage for 48 h in preservation solution after 0.5 Gy irradiation was significantly lower than that after sham irradiation. These findings indicate that the consumption of glutathione decreases the total level of glutathione in liver grafts and inhibits lipid peroxidation during storage.

In addition to measurement of the biochemical activity of molecules involved in oxidation, we also examined histological changes in hepatocytes after storage. These data indicated that hepatocytes stored in saline solution were vacuolated following irradiation at all intensities. In contrast, hepatocytes stored in preservation solution were not vacuolated following any irradiation. These results suggest that storage of liver in saline solution is of no benefit for future use of the liver for transplantation in spite of the increase in antioxidative function.

The data presented in this study provide an essential basis for future studies aimed at determination of the possibility of remission of ischemia-reperfusion injury in livers after transplantation.
