Summary In the present study, we investigated the effect of interferon-gamma (IFN-γ) on cellular calcium ion concentration [Ca²⁺], and inositol 1,4,5-trisphosphate (Ins 1,4,5-P₃) formation in the human renal carcinoma cell line CaKi-1. We also examined the possible role of a Ca²⁺-dependent mechanism during IFN-γ-induced intracellular adhesion molecule 1 (ICAM-1) antigen expression. IFN-γ caused a rapid concentration-dependent increase in [Ca²⁺], which was partly inhibited by diltiazem, a calcium channel blocker, TMB-8, an inhibitor of intracellular calcium redistribution, and in calcium-free medium. IFN-γ caused a fourfold increase in Ins 1,4,5-P₃ formation. The induction of ICAM-1 antigen expression was synergistically enhanced by 4-bromocالium ionophore A23187. Finally, the calcium antagonists diltiazem, TMB-8 and EGTA, as well as two potent inhibitors of Ca²⁺-dependent kinases, calmidazolium (R24571) and W7, had no or only a minor inhibitory effect on IFN-γ induction. Our data suggest that IFN-γ increases [Ca²⁺] in CaKi-1 cells by stimulating influx of Ca²⁺ and release of Ca²⁺ from intracellular stores, possibly via Ins 1,4,5-P₃ formation. IFN-γ signal transduction in our model may not be limited to an increase in [Ca²⁺], and Ins 1,4,5-P₃, since IFN-γ-induced ICAM-1 antigen expression was abrogated to a minor degree by calcium antagonists and not coupled to Ins 1,4,5-P₃ formation.

IFN-γ is an inflammatory cytokine that is capable of enhancing anti-tumour immune response by inducing the surface expression of different antigens, including intercellular adhesion molecule-1 (ICAM-1) and HLA class II, on tumour cells (Mortarini et al., 1960; Azuma et al., 1992). The signal transduction pathways used by IFN-γ to modulate antigen expression have been examined previously, but are still not well understood. However, a constant finding has been the activation of the Ca²⁺ phospholipid-dependent protein kinase C (PKC) by IFN-γ in both normal and neoplastic cells (Fan et al., 1988; Griffiths et al., 1990; Renkonen et al., 1990; Hansen et al., 1993). In the U937 macrophage cell line (Klein et al., 1990) and in human endothelial cells (Renkonen et al., 1990), IFN-γ-induced PKC activation has been shown to be accompanied by inositol 1,4,5-trisphosphate (Ins 1,4,5-P₃) formation. These studies suggest that IFN-γ receptor activation results in the cleavage of phosphatidylinositol bisphosphate into diacylglycerol and Ins 1,4,5-P₃, by phospholipase C (Downes & Macphee, 1990). While diacylglycerol can activate PKC, Ins 1,4,5-P₃ can increase cellular calcium ion concentration, [Ca²⁺].

We have recently shown that IFN-γ can activate PKC in the human renal carcinoma cell line CaKi-1 (Hansen et al., 1993). However, this activation was not related to IFN-γ-induced ICAM-1 antigen expression, indicating that alternative signalling pathways may be stimulated, including other Ca²⁺-dependent kinases. To our knowledge, there are no previous studies which have investigated the ability of IFN-γ to increase [Ca²⁺], and Ins 1,4,5-P₃, formation in human renal carcinoma cells.

In the present study we examined the role of Ca²⁺ and Ins 1,4,5-P₃ as secondary messengers during IFN-γ signalling in CaKi-1 cells. Furthermore, the possible role of a Ca²⁺-dependent mechanism during IFN-γ-induced ICAM-1 antigen expression was evaluated, since this adhesion molecule can augment anti-tumour immunity.

Materials and methods

Reagents

Human recombinant IFN-γ (1–5 x 10⁵ units per mg of protein) designated IFN-γ 4A was purchased from Amersham International (Denmark). The calcium ionophore, 4-bromocalium ionophore A23187 (bromo-A23187), diltiazem, EGTA (N,N,N',N'-tetraacetic acid), TMB-8 [3, 4, 5-trimethoxybenzoic acid S-(diethylamino)octyl ester], R24571 (calmidazolium), W7 (N-6-aminohexyl-5-chloro-1-naphthalenesulfonamide hydrochloride) and compound 48/80 (condensation products of N-methyl-p-methoxy-phenethylamine with formaldehyde) were obtained from Sigma (St Louis, MO, USA). IFN-γ was stored at 2–4°C diluted to 10⁶ or 10⁵ units ml⁻¹ in McCoy’s 5a medium containing 10% fetal bovine serum (FBS) (Gibco, Paisley, UK). Bromo-A23187 and R24571 were dissolved in dimethylsulphoxide (DMSO) and 1 mg ml⁻¹ stock solutions were stored at −80°C. All other drugs were dissolved in water and 1 mg ml⁻¹ stock solutions were stored at −20°C. The final concentration of DMSO did not exceed 0.3% and cultures containing appropriate quantities of diluents were run in parallel to control for minor effects.

Cell cultures

The human renal carcinoma cell line CaKi-1 was kindly provided by J. Fogh (Novo Nordisk, Gentofte, Denmark) and was originally isolated and characterised by the late J. Fogh (Memorial Sloan Kettering, Rye, NY, USA; Fogh & Trempe, 1975). The cells were maintained in McCoy’s 5a medium (Gibco) supplemented with 10% fetal bovine serum (FBS) (Gibco), 2 mM glutamine (Gibco) and 100 IU ml⁻¹ penicillin/streptomycin (Gibco). Cultures were incubated at 37°C in a 95% air, 5% carbon dioxide humid incubator.

Intracellular Ca²⁺ measurements

Confluent monolayers of CaKi-1 cells were detached with 3 mM EGTA in Hanks’ balanced salt solution without Ca²⁺/Mg²⁺/phenol red pH 7.4 (HBSS) (Gibco) for 20 min at 37°C, washed twice and allowed to settle for 2 h in McCoy’s 5a
medium. Cells from 2–3 flasks (1 x 10^7) were pooled in McCoy's 5a medium plus 0.5% bovine serum albumin (BSA) (Sigma) and loaded with 2 μM of the fluorescent dye, fura-2/AM (Molecular Probes, OR, USA). The rise in [Ca^{2+}] was measured as previously described for fibroblasts (Bouachelouche et al., 1988). The time course of changes in fluorescence was measured with a Hitachi F-4000 spectrofluorimeter using a single excitation and emission wavelength of 340 and 510 nm respectively. Drugs were added as indicated.

**Radioligand assay measurement of In 1.4.5-P_3**

Cellular In 1.4.5-P_3 was measured initially using a competitive binding assay (Challis et al., 1988; Palmer et al., 1989) (Amersham International, Denmark). Briefly, confluent CaKI-1 cells in 75 cm² flasks (10⁷ cells) were incubated with 10 mM inositol in 4 ml of McCoy's for 1 h, washed with McCoy's and subsequently incubated in 4 ml of McCoy's with 10 mM inositol and 10 mM lithium chloride for 30 min at 37°C. After washing, cells were centrifuged at 1,000 g for 15 min at 4°C. The supernatants were decanted and the pellets resuspended in ice-cold 15% TCA for 20 min. The pellet suspension was then mixed, centrifuged at 1,000 g for 15 min at 4°C and pooled with the corresponding supernatants. The TCA supernatants were extracted four times with 5 ml of anhydrous diethyl ether and adjusted to pH 7.5 with sodium bicarbonate. Sample aliquots (100 μl) were mixed with equal amounts of d-myo-[3H]Inositol 1.4.5-P_3 and bovine adenine In 1.4.5-P_3, binding protein, vortexed and incubated for 15 min on ice. The samples were then centrifugated at 1,000 g for 30 min at 4°C. The supernatants were decanted and the pellets resuspended in scintillant. Radioactivity was then measured by liquid scintillation counting and In 1.4.5-P_3 determined by comparison with a standard curve containing 0.19, 0.38, 0.76, 1.5, 3.1, 6.2, 12.5 and 25 pmol of In 1.4.5-P_3. Results are expressed in pmol of In 1.4.5-P_3 per 10⁴ cells.

**Analysis of inositol phosphates by column chromatography**

To confirm the binding assay, In 1.4.5-P_3 was measured by fast protein liquid chromatography (FPLC) on a Pharmacia Mono-Q anion-exchange column as described by Chew and Buse (1990). Briefly, for each reaction condition 10⁷ CaKI-1 cells in 75 cm² flasks were incubated with d-myo-[3H]inositol (5 μCi ml⁻¹) for 12 h in an atmosphere of 5% carbon dioxide at 37°C. Cells were then incubated for 30 min with 10 mM cold inositol and 10 mM lithium chloride in McCoy's at 37°C. After incubation cells were washed three times with McCoy's, reincubated with 10 mM lithium chloride in McCoy's for 10 min and stimulated with IFN-γ in 4 ml of McCoy's. The reaction was stopped with 2 ml of ice-cold 15% TCA. The cells were then transferred to cryotubes and TCA supernatants were extracted as described for the radioligand assay measurements of In 1.4.5-P_3 (see above). Sample aliquots (200 μl) containing the water-soluble inositol phosphates were separated using the Mono-Q anion-exchange column equilibrated with an ammonium formate (M)/formic acid (0.1 M) gradient and an FPLC (Pharmacia) system (Chew & Brown, 1986). Fractions of 3 ml were collected and radioactivities measured by liquid scintillation counting. Three major peaks of radioactivity were eluted from the column. These peaks coeluted with [3H]-labelled inositol standards (Du Pont/Dupharma, Denmark) of inositol 1-monophosphate (In 1-P), inositol 1,4-bisphosphate (In 1,4-P_2) and In 1.4.5-P_3 (Chew & Brown, 1986; Bouachelouche et al., 1990).

**Cell viability**

Cell viability was assayed by determining trypan blue exclusion microscopically and scoring a field of approximately 100 cells (Schlager & Adams, 1983).

**Total protein synthesis measurement**

The effect of calcium and protein inhibitors on total protein synthesis was analysed as described by Ritchie et al. (1991). Briefly, CaKI-1 cells were grown for 48 h in 24-well plates in McCoy's 5a medium containing 2 mM glutamine, 100 IU ml⁻¹ penicillin/streptomycin and 10% FBS. Labelling was achieved by incubating cells for 24 h with 20 μCi ml⁻¹ [35S]methionine with or without test agents. After labelling, the cells were placed on ice and washed twice with ice-cold HBSS. They were lysed in 500 μl of lysis buffer (50 mM Tris pH 8.5/0.5% Triton X-100/0.25% deoxycholate/10 mM EDTA/1 mM phenylmethylsulphonyl fluoride) for 15 min on ice. Lysates were transferred to tubes and a second aliquot of lysis buffer was added to the wells. Lysates were pooled and cleared by a 10 min centrifugation at 4°C. Aliquots of 250 μl were withdrawn from the supernatants to which 250 μl of 20% TCA was added. After a 20 min incubation on ice, the precipitates were transferred to glass microfilter discs on a vacuum manifold and washed with 5% cold TCA. Filters were dried and radioactivity was measured by liquid scintillation counting. The means of triplicate experiments are expressed as percentage protein synthesis compared with control cells.

**Flow cytometric analysis of ICAM-1 antigen**

At confluent monolayer in 75 cm² tissue flask, CaKI-1 cells were obtained for subculture by addition of 0.15% trypsin (Gibco) in calcium-free phosphate buffer (pH 7.2), blocked by McCoy's 5a with 10% FBS and the detached cells centrifuged and resuspended in fresh medium. A volume of 1 ml of a 10⁷ cells ml⁻¹ suspension was seeded in 25 cm² tissue flasks (Nunc). After 48 h of culture, cells were treated with IFN-γ, bromo-A23187, diethylazem, EGTA, TM-8, R24571 and W7 in the indicated concentrations, concentrations and time courses. After stimulation, cells were washed twice with HBSS/1% BSA. After washing, cells were detached by incubation in 2 ml of 1 mM EDTA in HBSS/1% BSA for 30 min at 37°C. The supernatants were transferred to 12 × 75 mm polystyrene tubes (Falcon, Becton Dickinson) and incubated for 30 min at 4°C in the dark with fluorescein isothiocyanate (FITC)-conjugated monoclonal anti-ICAM-1, clone 84H10 (Makgoba et al., 1988) (Immunotech, Marseilles, France), diluted 10 μl in 10 μl HBSS. After staining, cells were washed twice with HBSS/1% BSA by centrifugation at 300 g for 5 min and resuspended in 500 μl of fixation buffer (HBSS with 1% paraformaldehyde, pH 7.4). Analysis of fluorescence was performed on a FACSscan (Becton Dickinson, Mountain View, CA, USA). The background number of fluorescent cells (no relevant monoclonal antibody) was generally adjusted to less than 1% and the relative mean fluorescence intensity of positive cells (MFI) was measured. The irrelevant mouse IgG1 FITC-conjugated antibody X927 (Dako, Denmark) was used as a negative control. All MFI values are presented in a linear scale (Figure 5a-f).

**Assay of protein kinase A activity**

Recent data suggest that cAMP-elevating agents can induce ICAM-1 antigen expression in human glioma cells (Bouillon et al., 1992). In order to evaluate the significance of cAMP-dependent protein kinase (PKA) inhibition by the two modulators of Ca^{2+}-binding proteins used in this study, namely R24571 and W7, PKA activity was assayed upon IFN-γ stimulation. CaKI-1 cells were grown to a confluent monolayer in 75 cm² flask with McCoy's 5a medium supplemented as described above. Following stimulation of the cells (10⁴) with IFN-γ, treatment was stopped by decanting...
the medium and rinsing the monolayers twice in ice-cold PBS. After rinsing, flasks were maintained at 4°C while cells were gently scraped in 4 ml of ice-cold extraction buffer (5 mM EDTA, 50 mM Tris, pH 7.5). The cells were homogenised for 15 strokes on ice in a precooled Dounce homogeniser and left on ice for 30 min. To remove cellular debris the homogenate was centrifuged at 2,000 g for 10 min. The supernatants were removed and assayed for PKA activity. PKA was measured by the incorporation of 32P from 100 μM [γ-32P]ATP (1 x 104 d.p.m. mmol⁻¹, Amersham) into each sample in the presence or absence of cAMP (40 nM) with or without the heat-stable rabbit skeletal muscle PKA inhibitor protein PKI (6–22)NH2 (4 μM in 50 mM Tris, pH 7.5) using the PKA assay system (3128SA, Gibco, Paisley, UK). Substrate phosphorylation in the presence of cAMP reflected the total amount of PKA in each sample. The background (substrate phosphorylation in the presence of PKI) was subtracted from each sample, and PKA activity was expressed as the percentage of activated PKA per total PKA.

Statistics
All results represent the mean ± s.d. of three different experiments. Data were analysed by Student's t-test. P < 0.05 was considered statistically significant.

Results
Effect of IFN-γ on [Ca2+]i and possible source of calcium increase
To determine the effect of IFN-γ on [Ca2+]i, cells were stimulated with 10, 50, 100 and 500 units ml⁻¹ IFN-γ and the fura-2/AM-fluorescence was measured continuously with time. Figure 1a shows the dose- and time-dependent change: maximal levels were reached within 1 min of stimulation. In order to examine the ability of IFN-γ to increase [Ca2+]i by increasing Ca2+ influx from the medium as well as by releasing Ca2+ from intracellular stores, CaKi-1 cells were incubated with decreasing levels of Ca2+ before IFN-γ stimulation. Figure 1b shows the effect of IFN-γ (500 units ml⁻¹) in medium containing 1 mM Ca2+, 0.32 mM Ca2+, or free of Ca2+ (omission of calcium and addition of 0.40 mM EGTA). Reducing extracellular Ca2+ reduced the IFN-γ-induced rise in [Ca2+]i. In the absence of extracellular Ca2+, IFN-γ was still able to induce a [Ca2+]i response (Figure 1b; Medium: Ca2+ free), indicating Ca2+ release from intracellular stores. For comparison [Ca2+]i was measured after stimulation with bromo-A23187, a non-fluorescent calcium ionophore which increases [Ca2+]i by transporting calcium ions across biological membranes (Luckasen et al., 1974). Figure 1c shows that bromo-A23187 also increased [Ca2+]i by enhancing Ca2+ influx as well as by releasing intracellular Ca2+, since there was a significant, but reduced [Ca2+]i rise in medium free of Ca2+. The dependence of the IFN-γ-induced rise in [Ca2+]i on both Ca2+ influx and intracellular Ca2+ release was further supported by pretreating CaKi-1 cells with diltiazem (1 μM) or TMB-8 (75 μM) for 60 min before IFN-γ (500 units ml⁻¹) stimulation. Figure 1d shows the reduced rise in [Ca2+]i after blocking Ca2+ channels with diltiazem or intracellular Ca2+ redistribution with TMB-8 (Malagodi & Chiou, 1974; Owen & Villereal, 1982).

Effect of IFN-γ in inositol phosphate formation
The observed [Ca2+]i increase to IFN-γ stimulation in Ca2+-free medium and reduced response after TMB-8 pretreatment

indicates mobilisation of Ca\(^{2+}\) from intracellular stores. Therefore, we examined the ability of IFN-\(\gamma\) to increase intracellular levels of Ins 1,4,5-P\(_3\) (Table I). Table I shows that IFN-\(\gamma\) caused a concentration-dependent rise in Ins 1,4,5-P\(_3\), after 1 min stimulation. IFN-\(\gamma\) at 10 units ml\(^{-1}\) was enough for an almost maximal Ins 1,4,5-P\(_3\) production. Figure 2 illustrates the time course for Ins 1,4,5-P\(_3\) formation after stimulation with 500 units ml\(^{-1}\) IFN-\(\gamma\). Maximal levels were reached within 1 min. This corresponds with the time for maximal [Ca\(^{2+}\)]\(_i\) increase after stimulation with 500 units ml\(^{-1}\) IFN-\(\gamma\) (Figure 1a). In order to confirm the radioligand assay experiments (Table I), inositol phosphate formation was further analysed by FPLC (Table II). As shown in Table II, IFN-\(\gamma\) stimulated a significant increase in Ins 1-P and Ins 1,4,5-P\(_3\). There was a slight increase in Ins 1,4-P\(_2\), but this did not reach significant levels. Figure 3 shows a typical elution pattern of water-soluble inositol phosphates from Mono-Q columns. Thus, the FPLC analysis supports the radioligand assay experiments.

**Effect of calcium antagonists and protein inhibitors on cell viability and total protein synthesis**

To further investigate the role of Ca\(^{2+}\) and Ca\(^{3+}\)-dependent proteins in CaKi-1 cells during IFN-\(\gamma\) stimulation, we tested the effect of diltiazem, EGTA, TMB-8, and Ca\(^{2+}\)-binding protein inhibitors on IFN-\(\gamma\)-induced ICAM-1 antigen expression. Since ICAM-1 induction may depend on de novo protein synthesis, we assayed cell viability and total protein synthesis by trypan blue exclusion and metabolic labelling with \[^{35}\text{S}\] methionine to examine non-specific confounding effects of these drugs. Cell viability was unaffected by diltiazem (1 \(\mu\)M), EGTA (1 mM), TMB-8 (75 \(\mu\)M), R24571 (10 \(\mu\)M) or W7 (40 \(\mu\)M) treatment for 24 h. However, the calmodulin antagonist c4880 (Gietzen, 1983) reduced cell viability to 65–80% with signs of cell detachment at doses as low as 5 \(\mu\)M. In light of these results c4880 was excluded from the subsequent experiments. Figure 4 shows that, despite normal viability, pretreatment of CaKi-1 cells for 24 h with R24571 (5–10 \(\mu\)M) or W7 (20–40 \(\mu\)M) resulted in a 5–20% decreased protein synthesis. This was not the case for a 24 h pretreatment with diltiazem (1 \(\mu\)M), EGTA (1 mM) or TMB-8 (75 \(\mu\)M). Accordingly, protein synthesis was taken into account for normalising ICAM-1 antigen expression after R24571 and W7 inhibition (Ritchie et al., 1991).

**Effect of IFN-\(\gamma\) and bromo-A23187 on ICAM-1 antigen expression**

CaKi-1 cells were incubated with 10, 100 or 500 units ml\(^{-1}\) IFN-\(\gamma\) for 24 h. The data in Figure 5a show that IFN-\(\gamma\)
caused an increase in ICAM-1 antigen expression above control value at 100 and 500 units ml\(^{-1}\). IFN-γ at 10 units ml\(^{-1}\) had no effect on ICAM-1 antigen expression, although this dose yielded a clear \([Ca^{2+}]\) rise (Figure 1a) and an almost maximal Ins 1,4,5-P\(_3\) production (Table I). To investigate the role of calcium during ICAM-1 antigen induction we incubated cells with bromo-A23187 (0.5 μM) for 24 h. Bromo-A23187 significantly raised ICAM-1 antigen expression after 24 h (Figure 5b). Furthermore, combining full doses of IFN-γ (500 units ml\(^{-1}\)) and bromo-A23187 for 24 h significantly increased ICAM-1 antigen expression as compared with either agent alone (Figure 5b). This increment showed a slight synergy with a mean MFI of 272, since the sum of the two agents mean increment was 187 MFI.

**Effects of inhibition of calcium transients on IFN-γ-induced ICAM-1 antigen expression**

To determine the functional significance of extracellular calcium, cells were pretreated for 60 min at 37°C with the calcium channel blocker diltiazem (1 μM) or the Ca\(^{2+}\) chelator EGTA (1 mM), before addition of IFN-γ (500 units ml\(^{-1}\)) for 24 h. Figure 5c shows that, in the presence of diltiazem or EGTA, the mean MFI decreased from 531 ± 5

(1 μM), EGTA (1 mM) or d, TMB-8 (75 μM) on IFN-γ (500 units ml\(^{-1}\))-induced ICAM-1 antigen expression. Cells were pretreated with inhibitors for 60 min before IFN-γ incubation for 24 h. e, Effect of R24571 (10 μM) or f, W7 (40 μM) on IFN-γ (500 units ml\(^{-1}\)) induction. Cells were pretreated with inhibitors for 60 min before IFN-γ incubation for 24 h. ICAM-1 (MFI) was normalised according to total protein synthesis for R24571 (R24571-Normalised) and W7 (W7-Normalised). Data represent mean ± 1 s.d. of three experiments. *, **Significantly (P<0.05) higher than control and IFN-γ values respectively. ***Significantly (P<0.05) lower than IFN-γ value.
to 508 ± 7 and 493 ± 23 respectively. Despite statistical significance, these differences represent a weak non-conclusive decline in ICAM-1 antigen expression. The two antagonists had no effect on basal ICAM-1 antigen expression when used alone. To examine whether cellular calcium stores contribute to an increase in ICAM-1 antigen expression, CaKi-1 cells were pretreated with R24571, an anti-myocytic agent, and W7, a naphthalenesulphonamide, both potent inhibitors of Ca2+-binding proteins including PKC and calmodulin (Gietzen et al., 1981; Tanaka et al., 1983). Incubation of cells with R24571 (10 μM) or W7 (40 μM) for 60 min at 37°C had no inhibitory effect, while W7 only inhibited ICAM-1 antigen induction from 579 ± 1 (MFI) to 526 ± 22 (MFI), less than 10% (Figure 5c: IFN-γ + R24571-Normalised; and Figure 5d: IFN-γ + W7-Normalised). Since the differences in ICAM-1 antigen expression obtained upon IFN-γ treatment with or without calcium antagonists or protein inhibitors were weak, we examined the FACS profile (cell distribution) in addition to the MFI. Figure 6 illustrates representative traces from the FACS analysis indicating a highly homogeneous CaKi-1 cell population with minimal variation.

**Effect of R24571 and W7 on IFN-γ-induced ICAM-1 antigen expression**

Since ICAM-1 antigen expression may be induced by a [Ca2+] rise via activation of Ca2+-binding proteins, CaKi-1 cells were pretreated with R24571, an anti-myocytic agent, and W7, a naphthalenesulphonamide, both potent inhibitors of Ca2+-binding proteins including PKC and calmodulin (Gietzen et al., 1981; Tanaka et al., 1983). Incubation of cells with R24571 (10 μM) or W7 (40 μM) for 60 min at 37°C before addition of IFN-γ (500 units ml−1) for 24 h significantly reduced IFN-γ-induced ICAM-1 antigen expression (Figure 5c and d). However, when the total protein synthesis was taken into account for normalising ICAM-1 antigen expression, R24571 had no inhibitory effect, while W7 only inhibited ICAM-1 antigen induction from 579 ± 1 (MFI) to 526 ± 22 (MFI), less than 10% (Figure 5c: IFN-γ + R24571-Normalised; and Figure 5d: IFN-γ + W7-Normalised). Since the differences in ICAM-1 antigen expression obtained upon IFN-γ treatment with or without calcium antagonists or protein inhibitors were weak, we examined the FACS profile (cell distribution) in addition to the MFI. Figure 6 illustrates representative traces from the FACS analysis indicating a highly homogeneous CaKi-1 cell population with minimal variation.

**Effect of IFN-γ on PKA activity**

The control level of PKA activity in CaKi-1 cells was 6.0 ± 1.7%. This level was unaffected by stimulation with IFN-γ (500 units ml−1) for 15, 30 and 60 min, which yielded a PKA activity between 5.6 ± 1.4% and 7.8 ± 1.5%. These results support the hypothesis that the inhibitory effect of W7 on IFN-γ-induced ICAM-1 antigen expression was not caused by PKA inhibition. Hence, although cAMP-elevating agents can enhance ICAM-1 antigen expression, possibly via PKA (Bouillon et al., 1992), and although the potent calmodulin antagonist W7 may act upon PKA at 40 μM (Hidaka et al., 1984), this was unlikely to be the case in CaKi-1 cells.

**Discussion**

IFN-γ has been used alone or in combination with IFN-α as an immunotherapeutic agent in patients with renal cell carcinoma (Heicappell & Ackermann, 1990). One of the main antigenic effects of IFN-γ is the induction of cell-surface antigens, including ICAM-1, by activating different intracellular signal transduction pathways (Azuma et al., 1992; Bouillon et al., 1992; Hansen et al., 1993). In different cell types IFN-γ has been shown to activate PKC and/or increase Ins 1,4,5-P3 formation, indicating stimulation of the phosphatidylinositol-Ca2+ signal transduction pathway (Klein et al., 1990; Renkonen et al., 1990). We have recently demonstrated PKC activation as well as ICAM-1 antigen induction upon IFN-γ treatment of CaKi-1 cells (Hansen et al., 1993). Therefore, for the first time, we decided to examine the role of Ca2+ and Ins 1,4,5-P3 formation during IFN-γ-stimulation of this human renal carcinoma cell line, and relate these findings to ICAM-1 antigen induction.

Our findings showed a dose-dependent ability of IFN-γ to increase [Ca2+]i by inducing influx of Ca2+ and redistribution of intracellular Ca2+ stores. An influx of extracellular calcium after IFN-γ stimulation was supported by the inhibition of the rise in [Ca2+]i by removal of extracellular Ca2+ (Figure 1b) and by blocking calcium channels with diltiazem (Figure 1d). Redistribution of intracellular calcium was supported by the failure to completely block the increase in [Ca2+]i with Ca2+-free medium and by inhibition with TMB-8 (Figure 1d). Since TMB-8 is a known inhibitor of intracellular Ca2+ redistribution (Malagodi & Chiou, 1974; Owen & Villereal, 1982), and since Ins 1,4,5-P3 is a natural releaser of Ca2+ from intracellular stores (Downes & Macphee, 1990), IFN-γ-stimulated formation of Ins 1,4,5-P3 was examined. We found a significant increment in Ins 1,4,5-P3 using two independent methods, a radioisotope assay (Table I and Figure 2) and FPLC (Table II and Figure 3), which suggests that IFN-γ-induced redistribution of intracellular calcium may be mediated by this phosphatidylinositol metabolite. Usually high-performance liquid chromatography (HPLC) is used for separation of inositol phosphates (Burgess et al., 1985; Turk et al., 1986; Klein et al., 1990). However, the FPLC system appears to be superior in its ability to rapidly separate inositol phosphates while maintaining good resolution (Florholmen et al., 1989).

Often, only cell viability by dye exclusion or 'signs of toxicity' not otherwise specified are described when protein inhibitors are used in the study of antigen expression in cell cultures (Rothlein et al., 1988; Griffiths et al., 1990; Pedrinaci et al., 1989; Florida...
et al., 1990). However, this may be misleading since total protein synthesis can be inhibited despite normal cell viability, as shown for R24571 and W7 in CaKi-1 cells (Figure 4). The inhibition of total protein synthesis by these two inhibitors is a non-specific effect in relation to ICAM-1 antigen expression. Normalising ICAM-1 antigen expression to total protein synthesis revealed a markedly reduced effect, with only W7 reaching significant inhibition (Figure 5e and f). Similar findings have been obtained with the PKC inhibitors W7 and nairospore (Ritchie et al., 1991; Bouillon & Audette, 1993). Unfortunately, compound 48/80 could not be used because the cell viability was affected at even low doses.

The enhancement of ICAM-1 antigen expression in CaKi-1 cells by IFN-γ as assessed by FACS was approximately 1.3- to 1.4-fold. Although this represents a weak response as compared with other cell types, such as melanoma cells (Scheibenbogen et al., 1993), the FACS profile showed a highly homogeneous cell population (Figure 6). Furthermore, our data clearly demonstrated that IFN-γ-induced Ins 1,4,5-P_3 formation was not coupled to ICAM-1 antigen expression because 10 units ml^{-1} IFN-γ was enough for a maximal

maximal Ins 1,4,5-P_3 formation (Table I), whereas it had no effect on ICAM-1 antigen expression (Figure 5a). Also, in the presence of either dieflazim, EGTA or TMB-8, the IFN-γ-stimulated ICAM-1 antigen expression decreased by less than 15% (Figure 5c and d). Therefore, although statistically significant, such weak differences may not reflect a biochemically relevant phenomenon. Hence, the lack of coupling between Ins 1,4,5-P_3 formation and ICAM-1 antigen induction by IFN-γ as well as the lack of inhibition of this induction by calcium antagonists indicate that a Ca^{2+}-phosphatidylinositol signalling mechanism does not play a major role in IFN-γ-induced ICAM-1 antigen expression in CaKi-1 cells. This does not exclude the possibility that raising [Ca^{2+}], by mechanisms other than those applied by IFN-γ can potentiate IFN-γ induction. Thus, as illustrated in Figure 5b, raising [Ca^{2+}] with bromo-A23187 synergistically enhanced IFN-γ-induced ICAM-1 antigen expression. If IFN-γ raised ICAM-1 antigen expression by increasing [Ca^{2+}], then its combined effect with bromo-A23187 may have been predicted to be additive. The minor role of a Ca^{2+}-dependent mechanism during ICAM-1 antigen induction by IFN-γ was further supported by the weak inhibition of this induction by W7 (Figure 5f). The naphthaleen sulphonamide derivative W7 is a potent calmodulin antagonist, but may act upon several protein kinases at high concentrations (Tanaka et al., 1983; Hidaka et al., 1984). These include the cAMP-dependent PKA and PKC, besides its actions via calmodulin on calmodulin-dependent proteins. Since both cAMP-elevating agents and PKC activators can enhance ICAM-1 antigen expression (Griffiths et al., 1990; Bouillon et al., 1992) the W7 effect could have been ascribed to PKA and/or PKC inhibition, and not just calmodulin antagonism. However, IFN-γ did not stimulate PKA activity in CaKi-1 cells. Furthermore, although IFN-γ activates PKC in CaKi-1 cells as assayed by both histone and acetylated myelin basic protein peptide (4-14) substrate phosphorylation, inhibition of PKC with W7 had no effect on IFN-γ-induced ICAM-1 antigen expression (Hansen et al., 1993). In light of these findings, it is very unlikely that W7, a weaker PKC inhibitor than H7 and sphingosine, abrogated that IFN-γ induction by affecting PKA or PKC. The exact calmodulin-dependent proteins affected by W7 in our model are unknown, since calmodulin can activate a wide range of kinases and cyclases, including CaM kinase II, phosphorylase kinase, adenylate cyclase and guanylate cyclase (Brady et al., 1985). As discussed above, the non-specific effect of W7 on total protein synthesis was accounted for by normalising ICAM-1 antigen expression.

Our results partly agree with earlier studies on IFN-γ signalling in other cell types. In human endothelial cells, IFN-γ activates PKC and induces Ins 1,4,5-P_3 (Renkonen et al., 1990). Using similar radioligand assay conditions for Ins 1,4,5-P_3 quantitation as in our study, Renkonen et al. (1990) showed a maximal rise after 10 min of stimulation, with no significant rise within 1 min. This discrepancy, as compared with CaKi-1 cells, may relate to the malignant transformation itself or to the different embryonal origins of the cell lines. However, Renkonen et al. (1990) did not confirm their measurements of inositol trisphosphate formation with other independent assays, but were able to show a significant 1.4-fold increase in the efflux of 4^{-4}Ca^{2+} 5 min after IFN-γ stimulation. Furthermore, although W7 was shown to decrease IFN-γ-induced ICAM-1 antigen expression, this decrease was less than 20% and also not normalised to total protein synthesis. Therefore, the W7 effect may well have been non-specific. Our data are consistent with the findings of Klein et al. (1990), who demonstrated that IFN-γ caused a significant increase in Ins 1,4,5-P_3 formation within 1 min in U937 cells, using a identical radioligand assay and HPLC. The IFN-γ-induced rise in Ins 1,4,5-P_3 was correlated to a rise in [Ca^{2+}]. In agreement with our study, W7 had little or no effect on IFN-γ-induced antigen expression in U937 cells. In contrast, Ina et al. (1987) have shown that IFN-γ induces a rise in Ca^{2+} and HLA class II antigen expression in HL-60 cells, which again can be efficiently blocked by W7. In general, the reports on IFN-γ signalling agree that this cytokine can activate PKC and raise [Ca^{2+}], by increasing Ca^{2+} influx and/or by generating Ins 1,4,5-P_3. However, the effect of PKC inhibitors such as H7 or calmodulin inhibitors such as W7 on IFN-γ-induced antigen expression depends on the applied cell line and antigen under study (Ina et al., 1987; Griffiths et al., 1990; Klein et al., 1990; Hansen et al., 1993).

We conclude that IFN-γ can induce a rise in [Ca^{2+}], in CaKi-1 cells which is dependent upon Ca^{2+} influx as well as release of Ca^{2+} from intracellular stores, probably as a result of Ins 1,4,5-P_3 generation. This Ca^{2+}- Ins 1,4,5-P_3 response plays only a minor role during IFN-γ-induced ICAM-1 antigen expression and further studies are needed to identify other signal transduction pathways for IFN-γ in our model.

The authors wish to thank Annie Olsen and Lisbet von Kappelgaard for their skilled technical and secretarial assistance. This study was supported by the Director Jacob Madsen and wife Olga Madsen Foundation (A.B.H.), the Danish Hospital Foundation for Medical Research, Region of Copenhagen, The Faroe Islands and Greenland (A.B.H.), Torben Linnemann's grant for cancer research (A.B.H.) and the Danish Cancer Society (P.N.B.).
