High-spin states of \(^{84}\)Sr are populated through the reaction \(^{70}\)Zn \((\^{16}\)O, 4n\) \(^{84}\)Sr at the beam energy of 75 MeV. The measurements of excitation functions, \(\gamma-\gamma\) coincidences, directional correlations of oriented states (DCO) ratios and \(\gamma-\gamma\)-transition intensities are performed using eight anticompton HPGe detectors and one planar HPGe detector. Based on the experimental results, we establish a new level scheme of \(^{84}\)Sr, in which 12 new states and nearly 30 new \(\gamma\)-transitions are identified in the present work. The positive-parity yrast band is extended to spin \(I = 24^+\), while one negative-parity band is extended to spin \(I = 19^-\) and it is found that the even-spin and odd-spin members in high-spin states show the nature of signature staggering. The deformation of \(^{84}\)Sr is studied by calculating the total-Routhian-surfaces (TRS) of positive-parity yrast states in the cranked shell model formalism.

Nuclei with \(Z = 40\) and \(N = 45\) lie in a transitional region between the deformed nuclei and spherical ones. There exist collective bands in the nuclei such as some isotopes of Sr, Zr and Mo, and their structures also have single-particle features. The neutron-deficient strontium isotopes such as \(^{76,78}\)Sr are predicted to be deformed in the ground state with \(\beta_2 = 0.421^1\). On the other hand, \(^{84}\)Sr with a closed neutron shell at \(N = 50\) and a fairly good proton-subshell closure at \(Z = 38\), is found to be doubly magic and, hence, spherical. \(^{84}\)Sr, which has four neutron holes away from \(^{84}\)Sr, should display both collective and quasiparticle excitations; this makes it an interesting object of investigation. Dewald et al.,\(^1\) Kucharska et al.,\(^1\) Lister et al.,\(^3\) and Chattopadhyay et al.,\(^4\) have investigated the structure of \(^{84}\)Sr successively. More than ten years ago, low-spin states of \(^{90,94}\)Sr have been studied by Döring et al.,\(^7\) whose decay data suggested that the low-lying structures of \(^{90,94}\)Sr show many vibration-like features in a potential with modest deformation including candidates for two- and three-phonon multiplets. This vibration-like nature seems to evolve to a more rotational behavior with increasing angular momentum \(I\) and decreasing neutron number \(N\). So in order to study the structure feature of \(^{84}\)Sr in detail, the present experiment is designed to extend the level scheme of \(^{84}\)Sr to higher spin states. To analyze the deformation for the positive-parity state of this nucleus, total Routhian surface (TRS) calculations are carried out by means of the pairing-deformation-frequency self-consistent cranked shell model. Finally, the properties of the negative-parity bands of \(^{84}\)Sr are also discussed qualitatively.

Results

All events are sorted off-line into a 4096 × 4096 disc stored matrix on which the energy gates are set later. According to already existing level scheme\(^6\), we gate first on the strongest 793 keV \(\gamma\)-ray, and find that all of the relevant \(\gamma\)-transitions given in Ref. 6 are observed. Gated then on each of these relevant \(\gamma\)-transitions, the cascade relationship revealed in Ref. 6 is confirmed. In the coincidence spectrum gated by the 793 keV \(\gamma\)-transition, we also observe relatively strong 706, 759, and 988 keV \(\gamma\)-transitions, etc., and find that these \(\gamma\)-transitions are clearly visible in the coincidence spectrum gated by the 1001 keV \(\gamma\)-transition, as shown in Fig. 1(a). In order to confirm these \(\gamma\)-transitions belonging to the negative-parity band of \(^{84}\)Sr, we gate on the 988 keV \(\gamma\)-transition, and clearly observe 510, 793, 974, and 1001 keV \(\gamma\)-transitions, etc., which have already been confirmed to belong to \(^{84}\)Sr, but fail to observe other confirmed \(\gamma\)-transitions of the positive-parity band. In addition, we also observe relatively strong 759 and 1041 keV \(\gamma\)-transitions, etc., in the coincidence spectrum gated by the 988 keV \(\gamma\)-ray. In the
Coincidence spectrum gated by 510 keV, we observe relatively strong 759, 988, and 1041 keV \(\gamma\)-transitions, etc., besides the 208 and 417 keV \(\gamma\)-transitions. It can be seen that the 759, 988, and 1041 keV \(\gamma\)-transitions belong to \(^{84}\text{Sr}\) and their cascade relationship with the 510 keV \(\gamma\)-transition of the negative-parity band is confirmed. In the coincidence spectra gated by both the 759 and 719 keV \(\gamma\)-transitions, we observe the relatively strong 780 keV \(\gamma\)-transition in each case. From the fact that the sum of 719 and 780 equals the sum of 510 and 988, the cascade order of the 988 and 759 keV \(\gamma\)-transitions can be obtained. At the same time, we observe 624 and 417 keV \(\gamma\)-transitions in the coincidence spectrum gated by the 759 keV \(\gamma\)-transition, so their cascade order is also assigned. In the coincidence spectrum gated by the 719 keV \(\gamma\)-transition, we observe the strong 162 keV \(\gamma\)-transition. Gated on the 162 keV \(\gamma\)-transition, we prove that it has a cascade relationship with the 706, 719, and 1088 keV \(\gamma\)-transitions.

So far, the cascade relationships of strong \(\gamma\)-transitions observed in the coincidence spectrum gated by 793 keV are almost all assigned. In particular, the 706 keV \(\gamma\)-transition should be mentioned here. We can observe the strong 706 keV \(\gamma\)-transition in the coincidence spectra gated by 524 keV \(\gamma\)-ray of the positive-parity band and 1001 keV \(\gamma\)-ray, respectively. The 706 keV \(\gamma\)-ray can also be observed in the coincidence spectrum gated by the 624 keV \(\gamma\)-ray, and its intensity is much stronger than that of 162 and 1088 keV \(\gamma\)-rays, etc., in this spectrum. These indicate that the 706 keV \(\gamma\)-ray exists in two different cascades. The placements of 706 keV \(\gamma\)-transitions are confirmed through analyzing the coincidence spectrum gated by itself, shown in Fig. 1(b). In addition, we observe the strong 964 keV \(\gamma\)-transition and a string of cascade transitions that are established above it in the coincidence spectrum gated by the 808 keV \(\gamma\)-transition, as shown in Fig. 1(c).

In the coincidence spectrum gated by the 524 keV \(\gamma\)-transition of the positive-parity band, we observe not only 1202, 1205, and 1418 keV \(\gamma\)-transitions, but also 1414 and 1442 keV \(\gamma\)-transitions, and moreover find that the intensity of the 1414 keV \(\gamma\)-transition is stronger than that of the 1442 keV \(\gamma\)-transition. Note that this intensity relationship also appears in the coincidence spectra gated by the 1040 and 1116 keV \(\gamma\)-transitions, one may conclude that there exists a cascade relationship between the 1414 keV and 1442 keV \(\gamma\)-transition. Fig. 1(d) shows the high-energy cascade part of the coincidence spectra gated by 1414 keV. In the coincidence spectrum gated by 1086 keV, we observe not only 325, 1085, 1094, and 1274 keV \(\gamma\)-transitions which Lister et al.\(^5\) have already presented, but also 1450, 1752, and 2017 keV \(\gamma\)-rays, shown in Fig. 1(e). In the coincidence spectra gated by the 1268 and 1418 keV \(\gamma\)-transitions, we also observe 1450 and 1752 keV \(\gamma\)-transitions, and thus confirm their cascade order. In summary, 12 new levels and nearly 30 new \(\gamma\)-transitions are identified in the present work. Due to the weak intensities of the 1752 and 2017 keV \(\gamma\)-transitions, we use dashed lines to denote them in the level scheme proposed in the present work.

As mentioned above, in order to assign the multipolarity of these \(\gamma\)-transitions and then the spins and parities of the relevant states, the detectors are positioned around 38° (at 35°, 36°, 39°, 43°, and 143° with respect to the beam direction) and around 90° (at 81°, 90°, and 102° with respect to the beam direction) for deducing the DCO ratios. We in general gate on the strong E2 \(\gamma\)-transitions when the

**Figure 1 | Some examples of coincidence spectra gated by (a) 1001, (b) 706, (c) 808, (d) 1414, and (e) 1086 keV \(\gamma\)-rays, respectively.** The asterisk denotes the ray that does not belong to \(^{84}\text{Sr}\).
which is set to 793 keV to the 974 keV transition, and at last normalize the relative intensities of the γ-transitions to the intensity of the 793 keV transition, whereas 88Mo displays a certain degree of collectivity, just as its neighboring isotones. In the present work the observation of γ-transitions between the close-lying similar spin states of these two positive-parity bands demonstrates the existence of neutron-proton interaction, which is in agreement with the results of Chattopadhyay et al.8. All these are in good agreement with the calculation results carried out by Dewald et al. based upon interacting boson model (IBM) and those of Chattopadhyay et al.8. When the spins and parities of 148Sr reach above 14, it displays the properties of the rotational structure of deformed nuclei. The signature staggering for the γ-transitions energies within this band above 14° can be observed. It can be seen that it no longer maintains the shape of the ground state, i.e., the shape change occurs and then the rotation happens. It is worthy to mention that on the top of 14° 148Sr still exhibits the dominance of E2 γ-transitions, whereas 148Mo and 146Zr transfer to the strong M1 γ-transitions.

Discussion

The level scheme is compared with its neighboring even-even isotopes 78,80,82,86Sr. We find that N = 45 and N = 46 divide the structures of the nuclei with Z = 38 into two kinds of different properties, i.e., the structures of the nuclei with N < 45 exhibit rotational behavior, whereas the nuclei with N > 46 show strong vibrational behavior, see Refs. 11–13 for details.

The positive-parity states are extended to spin 24, especially four odd-spin states 15, 17, 19, and 21 are detected in the present work. As shown in Fig. 2, the ground-state band of 148Sr displays a certain degree of collectivity, just as its neighboring isotones. In the present work the observation of γ-transitions between the close-lying similar spin states of these two positive-parity bands demonstrates the existence of neutron-proton interaction, which is in agreement with the results of Chattopadhyay et al.8. All these are in good agreement with the calculation results carried out by Dewald et al. based upon interacting boson model (IBM) and those of Chattopadhyay et al.8. When the spins and parities of 148Sr reach above 14, it displays the properties of the rotational structure of deformed nuclei. The signature staggering for the γ-transitions energies within this band above 14° can be observed. It can be seen that it no longer maintains the shape of the ground state, i.e., the shape change occurs and then the rotation happens. It is worthy to mention that on the top of 14° 148Sr still exhibits the dominance of E2 γ-transitions, whereas 148Mo and 146Zr transfer to the strong M1 γ-transitions.

\(^a\), b), c), d), e), and f) gated by 793, 808, 719, 1086, 625, and 706 keV, respectively, when DCO ratios are deduced; g) obtained from the spectrum without subtracting the background.
To analyze the deformation for the positive-parity states of this nucleus in detail, total-Routhian-surface (TRS) calculations are carried out by means of the pairing-deformation-frequency self-consistent cranked shell model\textsuperscript{14,15}; i.e., pairing and deformation changing as a function of rotational frequency are determined self-consistently. In practical calculations, for a given frequency and deformation, pairing is treated self-consistently by solving the cranked pairing-correlated Hamiltonian and then the shape of a given state is determined by minimizing the calculated TRS (for details, see Refs. 14, 15). The single-particle energies are obtained with the nonaxial deformed Woods-Saxon (WS) potential\textsuperscript{16}. Particle number projection is approximated by the Lipkin-Nogami (LN) approach\textsuperscript{14,17,18}. Both monopole and quadrupole pairings\textsuperscript{19–21} are considered with the monopole pairing strength $G$ determined by the average-gap method\textsuperscript{22} and quadrupole strengths obtained by restoring the Galilean invariance of the paired many-body Hamiltonian\textsuperscript{19,20}. The quadrupole pairing has a negligible effect on energies but has an important influence on the collective rotation\textsuperscript{15,23}. In the cranked model calculation\textsuperscript{4,13}, the nuclear energy at zero frequency is calculated by the Strutinsky method\textsuperscript{24} with the standard liquid-drop energy\textsuperscript{25}. Calculations are performed in the lattice of quadrupole $(b_2, c_4)$ deformations with the hexadecapole $b_4$ variation. Samples of TRS are presented in Fig. 3 in the polar coordinate plane $(b_2, c_4)$ at specific rotational frequencies $v = 0.2, 0.4, 0.6,$ and $0.8$ MeV corresponding to a spin range of $I = (0–20)\hbar$, and the energy difference between neighboring contours is 200 keV. According to our TRS calculations, at a low rotational frequency, this nucleus is predicted to have an almost spherical shape and be soft in the $b_2$ and $c_4$. 

Figure 2 | The partial level scheme of $^{84}$Sr proposed in the present work. The transition energies are given in units of keV.
directions. With increasing frequency, the nucleus becomes slightly more rigid and has a deformed shape. In TRS calculations, at rotational frequency $\hbar\omega = 0.6$ MeV, the second minimum appears (see the lower left panel of Fig. 3). This minimum at $\beta_2 = 0.122$ and $\gamma = -4.759^\circ$ becomes yrast at $\hbar\omega = 0.7$ MeV and persists up to very high rotational frequency (see for example the lower right panel of Fig. 3).

The negative-parity states are extended to 10487 keV. The first negative-parity band consisting of $5^-$, $7^-$, $9^-$, and $11^-$ levels is not extended very high. We find only one 964 keV M1 $\gamma$-transition feeding the $11^-$ state in this band. We take the 414, 432, and 624 keV M1 $\gamma$-transitions, which Chattopadhyay et al. have already assigned through the lifetime measurements, as a part of a band based on the second $5^-$ level. The $6^-$, $7^-$, and $8^-$ states which lie above the second $5^-$ level have already been discovered by Dewald et al. and Chattopadhyay et al., and assigned spins and parities. We extend the negative-parity states to spins of $19^-$ and energy of 10487 keV. It shows that the $5^-$, $6^-$, $7^-$, and $8^-$ states indeed exhibit rotational behavior. This is consistent with the prediction of Dewald et al. But the M1 $\gamma$-transitions between the $10^-$, $9^-$, and $8^-$ states are not obvious; this phenomenon is consistent with the results by means

![Figure 3 | Total-Routhian-surfaces for $^{40}$Sr positive-parity states at $\hbar\omega = 0.2$ (upper left), 0.4 (upper right), 0.6 (lower left), and 0.8 MeV (lower right) corresponding to $I = (0–20)\hbar$. The black dot represents the overall minimum in each panel, and the contour lines are separated by 200 keV.](image-url)
of the deformed configuration-mixing shell model (DCM) calculations in the work of Sahu\textsuperscript{22}, who suspect the prediction made by Dewald et al.\textsuperscript{15}. The states above $1^-$ exhibit a very good collective vibration-like nature while the even-spin and odd-spin members of this band show the nature of signature staggering for the states above $1^+$.

As shown in Fig. 4, the levels of the negative-parity bands proposed in the present work are in agreement with DCM calculations, but the calculations haven’t given higher spin states. It should be noted that the $B(M1)/B(E2)$ ratios show an abrupt increase above the $1^-$ state, e.g. $B(780)/B(988) = 0.38$ ($\mu_e^2$/eV), compared with $B(624)/B(1041) = 28.24$ ($\mu_e^2$/eV). The observed increase in the $B(M1)/B(E2)$ values in the negative-parity band may probably be attributed to neutron holes occupying the $g_{92}$ high-$\Omega$ orbitals\textsuperscript{10}.

Figure 4 | DCM calculations for negative-parity states in $^{84}$Sr compared with the present experimental data.

### Methods

The high-spin states of $^{84}$Sr are populated through the reaction $^{70}$Zn (18O, 4n) $^{84}$Sr at the projectile energy of 75 MeV. The $^{18}$O beam is provided by HI-13 Tandem Accelerator at China Institute of Atomic Energy (CIAE). In order to increase the reaction yields in the experiment, the target consists of a stack of two thin self-supporting $^{18}$O foils with a thickness of about 400 $\mu$g/cm$^2$ each. The $^{18}$O was isotopically enriched to 99.3%. At first the excitation function is measured using beam energies of 67, 70, 75, 80, and 87 MeV, respectively. Then $\gamma-\gamma$ ($\gamma$ refers to the relative time difference between any two coincident $\gamma$ rays detected) coincidence measurements are performed at optimal beam energy of 75 MeV (beam intensity of $I = 8$–9 nA) using an array comprised of eight high-purity germanium (HPGe) detectors each with a BGO anti-Compton shield and one planar HPGe detector; each BGO/AC/HPGe detector has an efficiency of approximately 25% and the planar HPGe detector 20%. In the present work, in the analysis of the data, spectrum is produced with a gate on the prompt time peak and a time-random background matrix is subtracted. These detectors are placed at angles of $35^\circ$, $36^\circ$, $39^\circ$, $43^\circ$, $81^\circ$, $90^\circ$, $102^\circ$, $145^\circ$, and $159^\circ$ with respect to the beam direction, respectively, so that the directional correlation of oriented states (DCO) ratios can be deduced. The energy resolutions of the Ge detectors are between 1.8 and 2.2 keV at 1.333 MeV $\gamma$-ray energy. A total of $1.8 \times 10^6$ double- or higher-fold coincidence events are collected on the magnetic tapes in an event-by-event mode in the present experiment. The trigger condition for data acquisition is set such that events are recorded when at least two $\gamma$ rays in the Ge detectors are in prompt coincidence. The overall count rates collected by this array during the experiment are 500–600 events/s. The $\gamma$-ray energies and relative efficiencies are calibrated with $^{133}$Ba and $^{152}$Eu sources. In order to determine the multipolarity of the $\gamma$-ray transitions, three detectors near 90$^\circ$, 102$^\circ$ and 102$^\circ$ with respect to the beam axis are sorted against the other five detectors near 38$^\circ$ (at $35^\circ$, $36^\circ$, $39^\circ$, $43^\circ$ and $143^\circ$) to produce a two-dimensional angular correlation matrix from which it is possible to extract the average directional correlation of oriented state (DCO) intensity ratios. The $\gamma-\gamma$ coincidence data are analyzed with the Radware software package\textsuperscript{10}. The interpretation of DCO ratios is most straightforward when gating is carried out on stretched E2 transitions. In this case DCO ratios of about 1.0 and 0.5 are expected for stretched $\Delta I = 2$ and $\Delta I = 1$ transitions, respectively. Consequently, the inverse value of 2.0 is expected for a quadrupole transition gated on a dipole transition, and it is certainly 1.0 for a dipole transition gated on a dipole transition. If dipole-quadrupole mixing is included, then the DCO ratio for a $\Delta I = 1$ transition may vary between 0.2 and 1.8 depending on the amount of mixing and the nuclear alignment. Ambiguities may also occur since an unstretched pure $\Delta I = 0$ transition is expected to have a ratio slightly larger than 1, i.e., similar to a stretched E2 transition.

**Acknowledgments**

We would like to thank the operating staff of the HI-13 Tandem Accelerator at China Institute of Atomic Energy for providing the *O beam. The project is supported by Suranaree University of Technology under contract No. 15/2553, the National Natural Science Foundation of China under Grant No. 11065001, and the Foundation of the Education Department of Jiangxi Province under Grant No. GJJ12372.

**Author contributions**

S.S., G.H., X.K., Y.Y. and Y.W. wrote the main manuscript text, S.S. and G.H. prepared figures 1–2 and figure 4 and Z.B. prepared figure 3. X.W., L.Z., G.L. and C.H. designed experiment. All authors reviewed the manuscript.
