Voiding Dysfunction

Relationship between Proximal Urethrovaginal Space Thickness and Detrusor Overactivity in Women with Stress Urinary Incontinence

Department of Urology, Korea University Hospital, Seoul, Korea

Purpose: Detrusor overactivity (DO) cannot be predicted by clinical symptoms. Although it is possible that DO could be related to anatomical structures, scanty data exist about the relations between DO and anatomical structures. The aim of this study was to investigate anatomical differences in DO by measuring the thickness of the urethrovaginal space (UVS) and the urethral length (UL) in women with stress urinary incontinence (SUI).

Materials and Methods: Prospective data were collected from 72 women with SUI who underwent the midurethral sling operation. The subjects were divided into 2 groups according to the presence of DO by preoperative urodynamic study (UDS). UVS thickness was measured by trans-vaginal ultrasound. UL was measured by using a urethral catheter and a ruler. UVS thickness, UL, Q-tip, and urodynamic parameters, such as maximal urethral closure pressure (MUCP) and Valsalva leak point pressure, were compared between the two groups.

Results: Of 72 women, 23 patients had DO (31.9%). The proximal UVS was significantly thinner ($p < 0.001$) and the MUCP was significantly lower ($p=0.008$) in women with DO. According to the receiver operating characteristic (ROC) curve based DO prediction, the best cutoff value for UVS thickness was 0.84 cm (area under the ROC curve 0.763).

Conclusions: In this study, the proximal UVS was significantly thinner and the MUCP was significantly lower in patients with DO. A proximal UVS thickness of less than 0.84 cm was shown to be a predictive parameter for the development of DO on preoperative UDS. A large-scale prospective study is needed to validate these results.

Key Words: Urinary incontinence; Urodynamics

INTRODUCTION

Stress urinary incontinence (SUI) is due to the involuntary leakage of urine without bladder contraction secondary to a sudden increase in intra-abdominal pressure. It is the most common cause of urinary incontinence in adult women, in whom the incidence ranges between 40% and 65% [1].

Mixed urinary incontinence (MUI) is defined as involuntary leakage of urine associated with urgency and exertion, effort, sneezing, or coughing [2,3]. Its prevalence tends to increase with age [4]. It has been reported that between 30% and 50% of incontinent women experience MUI [5].

Detrusor overactivity (DO) has been proven through objective evaluation with urodynamic study (UDS), and not all MUI patients exhibit DO on UDS. When urinary incontinence is combined with DO, the patient’s quality of life decreases markedly and the efficacy and satisfaction with anti-incontinence surgery decline. We previously reported that women with MUI associated with DO had no differences in demographical and clinical variables before an-
ti-incontinence surgery but experienced less satisfaction after surgery than did those without DO [6].

Even if its causes have not been clearly delineated in SUI patients, leakage of urine occurs when urethral internal pressure becomes less than that of the bladder as intra-abdominal pressures increase from the weakening support structure of the urethra and bladder floor. In a study of the anatomical structures of the female lower urinary tract, Tunn et al demonstrated reduced urethral sphincter muscle thickness, changes of the levator ani muscle, and defects of the endopelvic fascia by performing magnetic resonance imaging (MRI) in women with SUI [7]. Choi et al reported that the urethral length (UL) was significantly shorter and the distal anterior vaginal wall was significantly thicker in women with SUI [8]. Therefore, it appears that the urethra and the tissues around the bladder floor play an important role in the pathogenesis of SUI.

The reason for the lack of reproducibility of DO in SUI is that SUI might also be the primary pathophysiologic mechanism responsible for MUI. In these women, the incompetent urethral sphincter and bladder neck allow urine to enter the proximal urethra during physical activity, eliciting an urethro-detrusor facilitative reflex that triggers involuntary detrusor contraction, causing urgency and urge urinary incontinence (UUI) [9]. Thus, there is a clinical discrepancy with symptomatic MUI and the actual presentation of DO on UDS.

On the other hand, research is lacking on the relations between DO and female anatomical structures. The aim of this study was to investigate whether female anatomical variables such as urethrovaginal space (UVS) thickness and UL are major factors influencing DO in women with SUI.

**MATERIALS AND METHODS**

Prospective data were collected from 72 women who underwent anti-incontinence surgery between March 2009 and March 2011 after approval of the Institutional Review Board of the Korea University Hospital. Investigations were carried out on all the subjects before surgery, which included a medical history, physical examination, symptom questionnaire, urinalysis and urine culture, Q-tip test, uroflowmetry, measurement of post-void residual urine volume, and UDS.

SUI was classified according to the Stamey grade into three categories. MUI was defined as involuntary urinary leakage associated with urgency and exertion, effort, sneezing, or coughing [2]. Patients with significant cystocele, pelvic floor prolapse, history of pelvic surgery, or psycho-neurologic conditions were excluded.

UDS included measurement of Valsalva leak point pressure (VLPP) and the maximal urethral closure pressure (MUCP) according to the guidelines of the International Continence Society [10]. DO was defined as involuntarily increased urination pressure by more than 15 cmH2O or increased with a sense of urinary urgency. Intrinsic sphincter deficiency (ISD) was defined as less than 60 cmH2O of VLPP. The MUCP was measured by inserting a 6 Fr urethral catheter into the bladder through the urethra and then pulling it from the bladder at a rate of 1.0 mm/s while injecting saline at a rate of 2.0 ml/s.

The thickness of the proximal UVS was measured by trans-vaginal ultrasound. After positioning the patient in the lithotomy position and inserting a 18 Fr urethral catheter and inflating it with 10 ml distilled water, an 8 MHz trans-vaginal probe was used to measure the thickness of the proximal UVS. The thickness of the proximal UVS was measured by the distance between the anterior vaginal wall and the catheter balloon, after halting the screen while...
viewing the vaginal wall and the catheter balloon on trans-vaginal ultrasound (Fig. 1). In addition, UL was measured as follows: first, the catheter balloon was pulled to the maximum to place it on the bladder neck; second, the gradation was marked on the part related to the urethral meatus; third, the catheter was removed by removing the balloon; fourth, the balloon was re-inflated outside the body. Finally, the UL was measured as the distance from the near side of the balloon to the urethral meatus with a ruler (Fig. 2).

Data are mean values±SD with median value or number of patients (%). UVS: urethrovaginal space, SUI: stress urinary incontinence, VLPP: Valsalva leak point pressure, MUCP: maximal urethral closure pressure, FUL: functional urethral length, PdetQmax: detrusor pressure at maximal urine flow rate, Pdetmax: maximal detrusor pressure, VV: voided volume, RV: residual urine volume.*: p<0.05 by Mann-Whitney U test.

RESULTS

The clinical characteristics of the 72 patients with SUI are summarized in Table 1 and Table 2. The mean patient age was 56.7 years (range, 32 to 76 years). Of the 72 women, 23 had DO (31.9%) by preoperative UDS and 49 patients did not (68.1%). Of the women with MUI, 31.4% had shown DO in the preoperative UDS. Urodynamic diagnosis of DO was predicted only by the existence of urgency symptoms (p=0.083). Other factors such as MUI or ISD were not meaningfully related with DO (Table 1).

The median age of the women with DO was 58.0 years.
FIG. 3. Receiver operating characteristic (ROC) curve of urethral length (UL), proximal urethrovaginal space (UVS), and maximal urethral closure pressure (MUCP) for detrusor overactivity (AUC: 0.567, 0.763, and 0.694, respectively).

DISCUSSION

MUI is defined as the state of SUI combined with UUI [3]. It is an unclear term because it can apply to a combination of incontinent symptoms (SUI and UUI) and to a combination of urodynamic conditions (urodynamic SUI and DO) in the same individual. Nevertheless, it is generally taken to represent symptoms. UDS is a useful method for studying women with MUI to determine the underlying pathology, particularly if the patients have not responded to conservative treatment. However, it is well known that up to 50% of patients with UUI do not demonstrate DO on UDS, just as not all women with SUI show leakage during UDS [11]. The reason is that with the urethro-detrusor facilitative reflex, SUI might also be the primary pathophysiologic mechanism responsible for MUI [9]. Also, in our study, there was a clinical discrepancy with symptomatic MUI and the actual presentation of DO on UDS.

It is generally known that 50% to 74% of patients with MUI can expect recovery of complete urinary continence because the factors of urinary urgency can be completely reversed by anti-incontinence surgery [12]. However, it has also been reported that patients with MUI experience a lower complete cure rate and satisfaction after surgery than do those with SUI only, with a rate of 36% to 66% [13]. It has also been reported that DO persisted after surgery in 4 of 12 patients with DO, and SUI persisted after surgery in 9 patients, whereas urinary incontinence resolved after surgery in 32 of 50 patients [13]. In short, a main risk factor for surgical failure for MUI is the existence of DO before surgery [14].

It has been reported that UVS thickness is related to sexual excitement [15,16]. A study that entailed trans-vaginal
ultrasonography was used to measure the thickness of the anterior vaginal wall to investigate the anatomical variability of a clitoris-UVS complex called the G-spot [17]. UVS can be correlated with complications after surgery, such as bladder irritability and tissue damage at the time of inserting the mesh required for sling surgery. Studies have been conducted on the thickness of the anterior vaginal wall in patients with SUI. It is assumed that the anterior vaginal wall around the distal urethra thickens as the distal urethral muscle becomes more involved with the closure of the urethra owing to a compensatory mechanism in patients with urinary incontinence, who have a more opened proximal urethral meatus related to the damage to the comparative rhabdoid urethral muscle and the volume loss of the connective tissue. However, accurate evidence is still lacking, even if the thickness of the UVS is assumed to be a factor that exerts influence on the pathogenesis of MUI. In this study, we found that the proximal UVS was significantly thinner in patients with DO. This suggests that the thinner the proximal UVS, the higher the possibility that ISD may be involved. Urinary leakage from the posterior urethra in SUI due to ISD stimulates the urethral sensory nerves to promote a voiding reflex that may then cause DO [9].

Considering the studies related to hormonal changes such as estrogen secondary to an increase in age and UVS thickness, it appears that the incidence of atrophic vaginitis increases due to a reduction in estrogen secretion due to menopause, and it can be a cause of reducing UVS thickness [18,19]. In addition, considering that symptoms of urinary urgency or UUI occurring after menopause were improved by estrogen replacement therapy [20], DO symptoms such as urinary urgency and UUI can occur due to a decrease in circulating estrogen secondary to menopause. At the same time, it can be considered that DO will occur more frequently in patients with a thinner UVS as the UVS becomes thinner as the result of atrophic vaginitis. However, a large-scale systematic study of this hypothesis should be conducted in the future.

A short UL has been reported to be a factor for SUI even if the correlation between UL and urinary incontinence is open to dispute [8]. Choi et al and Koo and Lee concluded that the length of a functional urethra in patients with urinary incontinence shown by UDS was significantly shorter than that of women without urinary incontinence [8,20]. On the other hand, there was a report that the rhabdoid urethral muscle was found to be substituted with hyper-dense tissue in patients with serious SUI through perineum ultrasonography [21], and Kondo et al asserted that a correlation between SUI grade and volume of the rhabdoid urethral muscle existed [22]. To sum up all these findings, it can be assumed that the UL is shorter in patients with SUI than in those without, owing to a reduction in the volume of the rhabdoid urethral muscle and weakening of the support structures around the bladder neck and urethra. However, research is scarce on UL in patients with MUI. The present study measured and compared the UL of patients with DO and that of patients without DO among SUI patients. Even if UL was shorter in patients with DO than in those without, there was no statistically significant difference between them. In addition, it has been shown that UL is negatively correlated with symptom duration.

This study demonstrated that the MUCP was significantly lower in patients with DO than in those without. The results of this study are consistent with those of an earlier study that reported that the rhabdoid urethral muscle was thinner and the MUCP was lower in patients with DO [23]. Awad et al reported that the urethral pressure profile in patients with DO was distinctively low on MUCP [24]. It was also mentioned that low MUCP was a factor predicting persistent urinary urgency following sling surgery in patients with MUI [25]. However, these findings are in contrast with the results of Woo et al [26]. Those authors stated that the bladder wall would become thicker when measured by ultrasonography and the detrusor pressure at maximal urine flow rate (PdetQmax) and MUCP were higher and the length of a functional urethra was longer in patients with DO than in normal individuals. This appears to be related to the increase in bladder outlet resistance caused by hypertrophy of the urethral sphincter and increased tension levels. MUCP was negatively correlated with age and positively correlated with PdetQmax and maximal detrusor pressure (Pdetmax) in this study. Because studies have generated different results on the correlation between the MUCP and DO, additional research is needed on the implications and correlations of these results.

There are several limitations to our study. First, a relatively small number of patients render it challenging to define the exact role of UVS and UL. Second, only one investigator conducted and interpreted the measurement of UVS thickness and the measurement of UL to reduce inter-individual errors. However, proximal UVS thickness (cm) showed a 2 mm difference for the average value even though there was statistical difference between the group with DO (0.5±0.2) and the group without DO (0.7±0.2). This error can occur according to what degree the experimenter pulls the urethral catheter. The methods of measuring UVS and UL should be validated by another method, such as MRI, but in clinical practice it is not easy to perform MRI in SUI patients.

The objective of this study was to characterize MUI in relation to DO by using UVS and UL by means of a relatively simple method. Large-scale prospective studies are needed to determine the critical role of UVS and UL in patients with DO.

**CONCLUSIONS**

Proximal UVS was significantly thinner and MUCP was significantly lower in women with SUI with DO than in women with SUI without DO. To achieve good results and patient satisfaction after anti-incontinence surgery, it is imperative to consider the anatomical differences between
patients with SUI preoperatively. Large-scale prospective studies are needed to establish the potential role of UVS and UL together with other anatomical structures.
