ABSTRACT

We use gravitational microlensing of the four images of the \( z = 0.658 \) quasar RXJ 1131–1231 to measure the sizes of the optical and X-ray emission regions of the quasar. The (face-on) scale length of the optical disk at rest frame 400 nm is \( R_{\lambda, O} = 1.3 \times 10^{15} \) cm, while the half-light radius of the rest frame 0.3–17 keV X-ray emission is \( R_{1/2, X} = 2.3 \times 10^{14} \) cm. The formal uncertainties are factors of 1.6 and 2.0, respectively. With the exception of the lower limit on the X-ray size, the results are very stable against any changes in the priors used in the analysis. Based on the H\( \beta \) line width, we estimate that the black hole mass is \( M_{1131} = 1.3 \pm 0.3 \times 10^{8} M_{\odot} \), which corresponds to a gravitational radius of \( r_g \approx 2 \times 10^{13} \) cm. Thus, the X-ray emission is emerging on scales of \( \sim 10 r_g \) and the 400 nm emission on scales of \( \sim 70 r_g \). A standard thin disk of this size should be significantly brighter than observed. Possible solutions are to have a flatter temperature profile or to scatter a large fraction of the optical flux on larger scales after it is emitted. While our calculations were not optimized to constrain the dark matter fraction in the lens galaxy, dark matter-dominated models are favored. With well-sampled optical and X-ray light curves over a broad range of frequencies, there will be no difficulty in extending our analysis to completely map the structure of the accretion disk as a function of wavelength.

Key words: accretion, accretion disks – black hole physics – gravitational lensing – quasars: individual (RXJ 1131–1231)

1. INTRODUCTION

A significant problem for theoretical studies of quasars is that we cannot spatially resolve their emission regions to test models (e.g., Blaes 2004). For example, in this paper we study the gravitational lens RXJ 1131–1231 (RXJ1131 hereafter), where we observe four images of a \( z = 0.658 \) quasar lensed by a \( z_l = 0.295 \) elliptical galaxy (Sluse et al. 2003). Based on the H\( \beta \) line width from Sluse et al. (2003) and a magnification corrected estimate of the continuum luminosity, we estimate that the black hole mass, \( M_{1131} \), is \( M_{1131} = (1.3 \pm 0.3) \times 10^{8} M_{\odot} \). This corresponds to a gravitational radius of

\[
r_g = \frac{G M_{BH}}{c^2} \approx (1.9 \times 10^{13}) \left[ \frac{M_{BH}}{M_{1131}} \right] \text{cm},
\]

which subtends only 0.001 h\(^{-1}\) micro-arc-seconds.

Gravity, however, has provided us with a natural telescope for studying the structure of quasars through the microlensing produced by stars in the lens galaxy (see the review by Wambsganss 2006). Microlensing has a natural outer length scale corresponding to the Einstein radius of the stars,

\[
(R_E) = D_{\text{OL}} \frac{4G (M) D_{\text{LS}}}{c^2 D_{\text{OL}} D_{\text{LS}}} \left[ \frac{M}{M_{\odot}} \right]^{1/2} \text{cm},
\]

where \( \langle M \rangle \) is the mean mass of the stars, and the distances \( D_{\text{OL}}, D_{\text{OL}}, \) and \( D_{\text{LS}} \) are the angular diameter distances between the observer, lens, and source. The microlenses also generate caustic lines on which the magnification diverges, which means that our gravitational telescope can, for all practical purposes, resolve arbitrarily small sources. The size of the source is encoded in the amplitude of the microlensing variability as the source, lens, and observer move relative to the caustic patterns—big sources have smaller variability amplitudes than small sources. The technique can be applied to any emission arising from scales more compact than a few \( R_E \).

If we model the accretion disk by a thermally radiating thin disk with a temperature profile of \( T \propto R^{-3/4} \) (Shakura & Sunyaev 1973),\(^8\) we can measure the scale \( R_H \) defined by the point where the photon energy equals the disk temperature, \( kT = \hbar c/\lambda_{\text{rest}} \), by two routes other than microlensing. First, we can estimate it from the observed flux at some wavelength. If the disk radiates as a black body, the surface brightness (Equation (5)) is fully specified by the temperature profile. The luminosity found by integrating over the surface brightness profile is proportional to the square of the disk size, so by comparing the observed and model fluxes we obtain a size estimate. For example, the \( I \)-band “flux size” is

\[
R_{\text{flux}} \approx 2.8 \times 10^{15} D_{\text{OL}} \frac{\lambda_{\text{obs}}^{-3/2}}{0.2 I^{-19}} \text{cm},
\]

where \( R_H = c/\lambda_H \) is the Hubble radius, \( i \) is the inclination angle of the disk, and the \( I \)-band magnitude zero point is 2409 Jy. Based on Hubble Space Telescope (HST) observations (Sluse

\(^7\) Using the Bentz et al. (2006) mass normalizations. For the Kaspi et al. (2005) normalization we obtain \( M_{1131} = (6.9 \pm 1.0) \times 10^8 M_{\odot} \), which is consistent with the earlier estimate of Peng et al. (2006) of \( 6 \times 10^7 M_{\odot} \) using the Kaspi et al. (2005) normalizations. We use the Peng et al. (2006) masses in Morgan et al. (2009) because we lacked spectra for the full sample of objects.

\(^8\) In our present analysis, we can neglect the drop in temperature and emission near the inner edge of the accretion disk as it has little effect on the results.
et al. 2006; S. Kozłowski et al. 2010, in preparation), we estimate that the magnification-corrected flux is \( I \sim 20.7 \pm 0.1 \) mag (\( \lambda_{\text{obs}} = 0.814 \) \( \mu \)m), which corresponds to an R-band (400 nm in the quasar rest frame) size of \( R_{\lambda, 0} = (3.5 \pm 0.2) \times 10^{14}(\cos i)^{-1/2} \) cm or about 18\( r_g \) using the \( \lambda^{4/3} \) scaling of Equation (4) to make the modest correction from \( I \) band to \( R \) band. The flux size depends on the mean magnification of the images as \( 1/\sqrt{\mu} \), which can introduce a ~50% systematic uncertainty into this size estimate. Second, thin disk theory predicts that

\[
R_{\lambda} \text{theory} = \frac{1}{\pi} \left[ \frac{45 \lambda r_g M}{16 \mu p} \right]^{1/3} = (2.5 \times 10^{15}) \left[ \frac{\lambda_{\text{rest}} \mu \text{m}}{1 \mu \text{m}} \right]^{4/3} \left[ \frac{M_{\text{BH}}}{M_{1131}} \right]^{2/3} \left[ \frac{L}{\eta L_E} \right]^{1/3} \text{ cm},
\]

which implies an R-band disk size \( R_{\lambda, 0} \text{theory} = 1.6 \times 10^{15} \) cm (82\( r_g \)) if the disk is radiating at the Eddington limit \( (L/L_E) = 1 \) with an efficiency of \( \eta = 0.1 \). Note that these two size estimates can be reconciled only if \( (L/\eta L_E)(M_{\text{BH}}/M_{1131})^2 \simeq 0.1(\cos i)^{-3/2} \), corresponding to a sub-Eddington accretion rate, an overestimated black hole mass, or a problem in the disk model since there is no evidence for the 1–2 mag of extinction an overestimated black hole mass, or a problem in the disk model since there is no evidence for the 1–2 mag of extinction in the lens galaxy that would be needed to raise the flux size (Equation (3)) up to that from thin disk theory (Equation (4)). Adding the inner disk edge or using a simple relativistic disk model (Novikov & Thorne 1973; Page & Thorne 1974) changes this problem little, as we discuss in Section 3.

The expected size of the X-ray emitting regions is more problematic because there is no comparably simple model for our theoretical expectations. There is a general consensus that the X-ray continuum emission is due to unsaturated inverse Compton scattering of soft photons by hot electrons in a corona surrounding the inner parts of the accretion disk (see the review by Reynolds & Nowak 2003), but the extent and geometrical configuration of the X-ray emission region is an open question. The X-ray continuum from the corona illuminates the disk to produce Fe Kα emission lines, whose broad widths indicate that they are generated close to the inner edge of the accretion disk (e.g., Fabian et al. 2005).

While there were a number of early attempts at estimating accretion disk sizes using microlensing (e.g., Wambsganss et al. 1990; Rauch & Blandford 1991; Wyithe et al. 2000b; Wambsganss et al. 2000; Goicoechea et al. 2003), it is only in the last few years that it has become possible to make large numbers of microlensing size estimates. In particular, Pooley et al. (2007) argue that the optical sizes estimated from microlensing must be considerably larger than the theoretical estimate in Equation (4). Morgan et al. (2009), in a more detailed analysis, found a relatively good agreement between the optical sizes estimated from microlensing and estimates based on Equation (4) and that the scaling of the sizes with black hole mass is consistent with the \( M_{\text{BH}}^{2/3} \) expected from thin disk theory if the quasars have similar Eddington ratios. However, both the microlensing and the theoretical size estimates led to predictions for the optical flux that were too large—matching the observed optical fluxes required a significantly smaller disk.

Recent studies have started to examine the temperature dependence of disks through the scaling of disk size with wavelength (Anguita et al. 2008; Poindexter et al. 2008; Agol et al. 2009; Bate et al. 2008; Floyd et al. 2009; Mosquera et al. 2009). Studies of the microlensing of the X-ray emission are more limited, but indicate that the X-ray emission is much more compact than the optical (Dai et al. 2003; Pooley et al. 2006, 2007; Kochanek et al. 2006; Morgan et al. 2008; Cartes et al. 2009), tracking much closer to the inner edge of the accretion disk. In this paper, we estimate the sizes of the optical and X-ray emission regions of RXJ1131 using microlensing. In Section 2, we describe the data and the analysis method. In Section 3, we discuss the results, their implications, and directions for further research. We use an \( \Omega_0 = 0.3 \) flat cosmological model with \( H_0 = 100h \) km s\(^{-1}\) Mpc\(^{-1}\) and \( h = 0.7 \).

2. DATA AND ANALYSIS

The optical data consist of the five seasons of R-band monitoring data described in S. Kozłowski et al. (2010, in preparation). For our present analysis we simply shifted the B–D light curves by their measured time delays to align them with image A. The X-ray data, all ACIS observations from the Chandra Observatory, consist of the epoch presented by Blackburne et al. (2006) plus the five epochs presented in Cartes et al. (2009). Each of the Cartes et al. (2009) epochs consisted of a 5 ks observation using ACIS-S3 in 1/8 sub-array mode from which we measure the 0.2–10 keV flux. Cartes et al. (2009) also reanalyzed the Blackburne et al. (2006) data to properly correct for the “pile-up” effect. While we include the optical data for image D, we do not use its X-ray fluxes in our analysis because we cannot presently be certain its flux ratios relative to A–C are unaffected by source variability given the roughly 3 month time delay between D and A–C (S. Kozłowski et al. 2010, in preparation). As we can see from Figure 4, the X-ray source must be more compact than the optical source because the X-ray flux ratios are dramatically more variable.

A full description of our microlensing analysis method is presented in Kochanek (2004) and Kochanek et al. (2006). In essence, we create the microlensing spatial magnification patterns we would see for a broad range of lens models and source sizes, then randomly generate light curves to find ones that fit the data well. We then use Bayes’ theorem to combine the results for the individual trials to infer probability distributions for physically interesting variables including the uncertainties created by all the other variables.

We fit the lens as in S. Kozłowski et al. (2010, in preparation), modeling it as an \( R_\gamma = 1.7 \) de Vaucouleurs model for the stellar distribution embedded in a Navarro–Frenk–White halo. We consider a sequence of models described by \( f_\gamma \), the fraction of mass in the stellar component relative to a constant mass-to-light ratio model with \( f_\gamma = 1 \) and no halo. We include models with \( f_\gamma = 0.1 \) to 1 in equal steps, and the time delay measurements favor \( f_\gamma \approx 0.2 \). These lead to the values for the convergence \( \kappa \), shear \( \gamma \), and fraction of the convergence in stars \( \kappa_\gamma/k \) given in Table 1.

The stars creating the microlensing magnification were drawn from a power law mass function \( dN/dM \propto M^{-1.3} \) with a ratio of \( M_{\text{max}}/M_{\text{min}} = 50 \) between the minimum (\( M_{\text{min}} = 0.11 \langle M \rangle \)) and maximum masses (\( M_{\text{max}} = 5.6 \langle M \rangle \)) that roughly matches the Galactic disk mass function (see Gould 2000; Poindexter & Kochanek 2009). We know from previous theoretical studies that the choice of the mass function will have little effect on our conclusions given the other sources of uncertainty (e.g., Paczyński 1986; Wyithe et al. 2000a). The mean mass \( \langle M \rangle \) is left as a variable with a logarithmic prior over the mass range \( 0.1 < \langle M/M_\odot \rangle < 1.0 \).
The macro models are parametrized by $f_\ast$, the fraction of mass in the de Vaucouleurs component relative to a constant $M/L$ model with $f_\ast \equiv 1$. The microlensing model parameters are the convergence $\kappa$, shear $\gamma$ and the fraction of the convergence in stars $\kappa_*/\kappa$.

For each model, we generated eight random realizations of the star fields near each image. The magnification patterns had an outer scale of $10(R_E) = 4.6(M/M_\odot)^{1/2} \times 10^{13}$ cm and a pixel scale of $10(R_E)/8192 = 5.6(M/M_\odot)^{1/2} \times 10^{13}$ cm $\simeq 3\sigma_g$, so we should be able to model sources as compact as the inner edge of the accretion disk. We modeled the relative velocities as in Kochanek (2004), where for RXJ1113 the projection of the cosmic microwave background dipole velocity (Kogut et al. 1993) on the lens plane is 47 km s$^{-1}$, the lens velocity dispersion estimated from the Einstein radius is 350 km s$^{-1}$, and the estimated rms peculiar velocities of the lens and source galaxies are 180 and 140 km s$^{-1}$, respectively.

The source model for both the optical and X-ray sources is a face-on disk with a temperature profile $T \propto R^{-3/4}$ radiating as a black body (Shakura & Sunyaev 1973), so the surface brightness profile of the disk is

$$I_\nu(R) = \frac{2hc^2}{\lambda^2} \left[ \exp((R/R_\ast)^{3/4}) - 1 \right]^{-1}$$

with the single parameter being the scale length $R_\ast$ whose theoretical value is given by Equation (4). While it is true that this profile lacks the central drop in emissivity and that it is not a physical model for the non-thermal X-ray emission, the microlensing analysis is not sensitive to these details. The estimate of the half-light radius ($R_{1/2} \simeq 2.44R_\ast$) is essentially independent of the assumed profile (Kochanek 2004; Mortonson et al. 2005). We used a $46 \times 61$ logarithmic grid of trial source sizes for the X-ray and optical sources with a spacing of 0.05 dex.

We do, however, allow for the possibility that fraction $f_{\text{opt}} = 0\%–40\%$ of the optical emission is generated on scales much larger than the disk and is unaffected by microlensing. Such large-scale emission could have two physical origins. First, the optical continuum can be significantly contaminated by emission lines, both the obvious broad lines and the less obvious Fe and Balmer pseudo-continuum emission ($\sim 30\%$ of the emission in some Seyferts; Maoz et al. 1993) that are believed to be produced on much larger scales than the disk. For our $R$-band light curves, there are no strong emission lines in the filter band pass, but the blue edge of the Balmer continuum emission ($\sim 6000$ Å) does lie inside the band pass (roughly 5700–7200 Å). Spectral decompositions by Sluse et al. (2007) indicate that the contamination is of order 20%–30%. Second, even if the observed photons were generated by the accretion disk, a fraction could be scattered on much larger scales, leading to an effectively larger source. These two possibilities are not equivalent, as the line emission is due to reprocessing of shorter wavelength UV photons rather than the observed $R$-band continuum.

A basic problem for any microlensing analysis is the degree to which the “macro” lens model correctly sets the average magnifications. Each light curve, $m_i(t) = s(t) + \mu_i + \delta\mu_i(t) + \Delta_i$ is defined by the source light curve $s(t)$, the macro model magnification $\mu_i$, the microlensing magnification $\delta\mu_i(t)$, and a possible offset $\Delta_i$. These offsets can be non-zero due to problems in the accretion disk, a fraction could be scattered on much larger scales, leading to an effectively larger source. These two possibilities are not equivalent, as the line emission is due to reprocessing of shorter wavelength UV photons rather than the observed $R$-band continuum.

Notes. The macro models are parametrized by $f_\ast$, the fraction of mass in the de Vaucouleurs component relative to a constant $M/L$ model with $f_\ast \equiv 1$. The microlensing model parameters are the convergence $\kappa$, shear $\gamma$ and the fraction of the convergence in stars $\kappa_*/\kappa$.
using only the “DC” flux ratios (e.g., Pooley et al. 2006, 2007; Bate et al. 2008; Floyd et al. 2009) require less data than our “AC” approach, but they can also lead to conclusions dominated by these systematic errors. The “AC” approach also has the advantage that including the effects of the velocities allows us to estimate source sizes in centimeters without simply assuming a mean mass \( \langle M \rangle \). However, when we use loose priors on the DC flux ratios, we lose significant information on the locations of the images relative to the magnified and demagnified regions of the patterns. As such, it is a conservative approach. We consider all four offset treatments in order to explore their consequences on estimates of the source size and the amount of dark matter in the lens.

We used eight statistical realizations of the microlensing magnification patterns for each of the 10 stellar surface densities \( f_s \) and for five unmicrolensed fractions of optical light \( f_{\text{no}} \). We modeled the data sequentially, making \( 10^6 \) trials for each optical source size and case, and then fitting each trial that was a reasonable statistical fit to the optical data to the X-ray data for each of the X-ray source sizes. In this second step, we considered both the case where the X-ray and optical share the same intrinsic flux ratios and where they are allowed to differ.

3. RESULTS AND DISCUSSION

Figure 1 shows the main result for the estimated size of the X-ray and optical emission regions. These combine all four treatments of the magnification offsets. Also note that in order to preserve the meaning of size ratios in Figure 1, we used the scale \( R_\lambda \) of a face-on disk for both. Physically, the X-ray emission is better characterized by its half-light radius, \( R_{1/2} = 2.44 R_\lambda \). The scale length of the thin disk also scales as \( \cos^{-1/2} \) if not viewed face on. We show the results for two different priors on the disk sizes, a logarithmic \( (P(R_\lambda) \propto 1/R_\lambda) \) and a uniform \( (P(R_\lambda) \propto \text{constant}) \) prior, and this has minor effects for the optical estimate and significant effects for the X-ray estimate. For the logarithmic prior we formally find that the likelihoods converge for small X-ray sizes when we use a linear prior but not for a logarithmic prior. A logarithmic size prior then will flatten for small source sizes. A logarithmic prior then favors these small scales compared to a linear prior, leading to significant differences. Thus, our lower limits on the size of the X-ray emission are at a minimum prior dependent. More conservatively, the results could be interpreted as providing only an upper bound on the size of the X-ray emitting region.

Figure 2 shows how the sizes depend on the priors, the treatment of the magnification offsets, and the fraction \( f_{\text{no}} \) of the optical emission that is unaffected by microlensing. The X-ray size is affected only by the choice of the prior. The optical size is only affected by \( f_{\text{no}} \). There are no significant differences between the results for the four magnification offset cases. In order to produce the same optical variability with a larger fraction \( f_{\text{no}} \), we must shrink the disk scale length \( R_\lambda \). Mortonson et al. (2005) argue that the effects of microlensing are largely determined by the half-light radius of the source, which is \( R_{1/2} = 2.44 R_\lambda \) in the limit that \( f_{\text{no}} = 0 \). As we increase \( f_{\text{no}} \), the disk scale length shrinks roughly by the amount needed to keep the half-light radius constant, with \( R_{1/2} = 5.87 R_\lambda \) when \( f_{\text{no}} = 0.4 \). Note, however, that the scaling for this particular model will break down when \( f_{\text{no}} = 1/2 \).

Only samples up to some minimum physical distance from a caustic crossing, then it will constrain sources sizes significantly smaller than that distance poorly and the likelihood function will flatten for small source sizes. A logarithmic size prior then favors these small scales compared to a linear prior, leading to significant differences. Thus, our lower limits on the size of the X-ray emission are at a minimum prior dependent. More conservatively, the results could be interpreted as providing only an upper bound on the size of the X-ray emitting region.

The X-ray size is more sensitive to the priors because the convergence of the probability distributions for small sources is poor when the light curve is sparsely sampled. We will generically find that the likelihoods converge for small X-ray sizes when we use a linear prior but not for a logarithmic prior. The problem is not due to the pixel scale of the maps, but due to the lack of a well-sampled peak in the X-ray data. Very small source sizes are constrained by the magnification peaks observed during a caustic crossing. If the light curve

\[ v \sim \sqrt{M} \]  

\[ r \sim f(M)^{1/2} \approx \sqrt{M} \]  

\[ \text{is essentially independent of } \langle M \rangle \text{ given a prior on the velocity.} \]
of microlensing (Anguita et al. 2008; Eigenbrod et al. 2008; Poindexter et al. 2008; Mosquera et al. 2009; Bate et al. 2008), but are not required. The one exception is Ford et al. (2009), who find a limit requiring a steeper temperature profile. Some of this information is also present in the overall spectral energy distribution, and it is a long-standing problem that the spectra of quasars do not match the predictions of thin disk theory (see Koratkar & Blaes 1999; Gaskell 2008).

Whether increasing $f_{\text{no}}$ helps to resolve the size discrepancies depends on the physical model for the contamination. Line emission is reprocessed shorter wavelength emission, so as we increase $f_{\text{no}}$ we are also reducing the fraction of the observed emission due to the disk and the flux size also shrinks as $(1 - f_{\text{no}})^{1/2}$. If, however, we view it as a scattering fraction $f_{\text{no}}$ of the continuum emission on some large scale, then the flux size estimate is unchanged and the effect helps to reduce the discrepancy. Resolving the discrepancy with $f_{\text{no}}$ would require that most of the optical emission does not reach us directly from the accretion disk.

While the source sizes show little dependence on the treatment of the magnification offsets, estimates of the amount of dark matter in the lens are sensitive to how strongly we constrain the models to match the observed macro model flux ratios, as illustrated in Figure 3. By leaving the offsets relatively free, so as to conservatively estimate the source sizes, we have not optimized the calculation for probing dark matter. The Case I and II models, where we very loosely constrain the allowed magnification offsets, marginally favor models with $f_s \simeq 0.3$. The Case I and II' models, where we only accept small offsets, favor the same dark matter-dominated model more strongly. This range for $f_s$ is also that favored by the time delays measurements from S. Kozlowski et al. (2010, in preparation). Note, however, that we are not in the “lagoon and caldera” regime for the microlensing patterns noted by Schechter & Wambsganss (2002) because of the very high magnifications ($\mu \sim 50$ for image A at low $\kappa_s/\kappa$ rather than $\mu \sim 10$).

Figures 4–6 show several examples of model light curves that fit the data reasonably well. These were also selected to have velocities consistent with mean masses of order 0.1–1.0 $\text{M}_\odot$. The solutions are not unique, but they illustrate how simple changes in the source size dramatically alter the amplitude of the variability. A common theme to the solutions is that the A and B images are generally required to lie in “active” regions of the patterns in order to produce such large changes in the X-ray fluxes. This means that we can expect the dramatic variability observed in this system to continue for an extended period of time (1–10 years). It is also interesting to note that significant changes in the optical fluxes are also likely. The larger optical source size washes out the effects of the closely spaced caustics that help to drive the X-ray variability. But the overall changes between the high magnification ridges and the demagnified valleys are still significant, and we should see overall changes in the optical fluxes several times those observed to date.

The implications of these results for theoretical models are mixed. The size of the disk is grossly similar to that expected from thin disk theory, and as we have summarized in Morgan et al. (2009), we find disk sizes that scale with black hole mass and optical wavelength roughly as expected (Equation (4)). We also find that the X-ray emission arises from significantly closer
The sizes of the X-ray and optical emission regions of RXJ 1131–1231

---

**Figure 4.** X-ray (top) and R-band optical (bottom) flux ratios between the A−B and B−C images along with the tracks across the microlensing patterns for images A (left) and B (right). The large circle shown on each pattern is the Einstein radius, while the small circles have the half-light radius of the optical disk and are shown at the positions corresponding to the epochs of the X-ray observations. The overall length of the line corresponds to one decade of motion. Darker colors represent logarithmically higher magnifications with an overall magnification range from 1/30 to 30. This is a Case I example with fairly large differential offsets. It has a high stellar surface density ($f_\ast = 0.7$), a large amount of smooth optical emission ($f_{\text{n0}} = 0.4$), and the X-ray source is 14 times smaller than the optical.

To the expected inner edge of the accretion disk than the optical emission, as we might expect for a hot corona. The optical size is broadly consistent with the expectations for an Eddington luminosity black hole with a mass estimated from the emission line widths (Equation (4)). This differs from the conclusion by Pooley et al. (2007) for this object because they used a significantly lower estimate of $M_{\text{BH}} = 2.5 \times 10^7 M_\odot$ for the black hole mass based on the quasar luminosity rather than line width measurements, and because their approximation for the microlensing size is somewhat large compared to a full calculation. If we use their preferred values of $L/L_E = 1/4$ and $\eta = 0.15$, they would estimate that $R_\lambda = 2.8 \times 10^{14}$ cm instead of $R_\lambda = 8.5 \times 10^{14}$ cm, and their microlensing size estimate corresponds to $R_\lambda = 5 \times 10^{15} (M/M_\odot)^{1/2}$ cm instead of our more quantitative estimate of $R_\lambda = 1.3 \times 10^{15}$ cm. Thus, where Pooley et al. (2007) find that the two sizes disagree by a factor of 18, we find that they differ by a factor of 50 that is well within our uncertainties. However, our estimate of the size, whether from theory (Equation (4)) or from microlensing, is inconsistent with that expected for a thermally radiating disk with a $T \propto R^{-3/4}$ temperature profile and the observed optical flux (Equation (3)).

Should we conclude that the thin disk model is wrong or simply that we have oversimplified the optical radiation transfer? We considered contamination by line emission or scattering of the optical photons, finding that this can modestly reduce the disk size for the range where up to 40% of the optical emission does not come directly from the disk. Our simple emission model neglects the disk atmosphere and heating of the outer disk by radiation from the inner disk, all processes which would tend to make the optical emission region larger than the point where the disk has a temperature matching the photon wavelength without any change in the underlying properties of the disk. Many of these effects are included in recent disk models such as Hubeny et al. (2001) or Li et al. (2005). Suppose we consider a face-on disk with $M_{\text{BH}} = 10^8 M_\odot$, $M = 0.09 M_\odot \text{ yr}^{-1}$ (40% of Eddington) and a BH spin of $a = 0.998$. For this mass and accretion rate, our simplified model in Equation (4) gives $K_{\lambda}^{\text{theory}} / r_g = 41$ and $R_{1/2}^{\text{theory}} / r_g = 2.44 K_{\lambda}^{\text{theory}} / r_g = 100$ for $\lambda_{\text{obs}} = 0.81 \mu$m. If we compute the same two scales using the Hubeny et al. (2001) models,
we find that the value of $R_{\lambda}^\text{theory}$ is moderately sensitive to the assumptions of the model, with $R_{\lambda}^\text{theory}/r_g = 36$ (34) for a non-relativistic (relativistic) disk radiating as a black body, and $R_{\lambda}^\text{theory}/r_g = 28$ (26) for a non-relativistic (relativistic) disk with a non-LTE (NLTE) atmospheric model, while the half-light radius depends little on the model, with $R_{1/2}^\text{theory}/r_g = 114$ (117) for a non-relativistic (relativistic) disk radiating as a black body, and $R_{1/2}^\text{theory}/r_g = 99$ (102) for a non-relativistic (relativistic) disk with a NLTE atmospheric model. Since the half-light radii are similar, the microlensing effects will be similar. In no case are the differences large enough to reconcile all the size estimates.

A flatter temperature profile than $T \propto R^{-3/4}$ would help, since at fixed total flux the half-light radius increases. For example if $T \propto R^{-1/2}$, the flux would be only 20% of our standard profile for the same half-light radius. Indeed, such a flat temperature profile would also come much closer to matching the observed spectra of quasars (e.g., Koratkar & Blaes 1999; Gaskell 2008) and would be representative of models dominated by irradiation. In general, however, current microlensing results on temperature profiles do not favor such flat profiles even if they generally allow somewhat flatter profiles (e.g., Anguita et al. 2008; Eigenbrod et al. 2008; Poindexter et al. 2008; Mosquera et al. 2009; Bate et al. 2008; Floyd et al. 2009).

The key to disentangling these problems is to expand the measurements over a broad range of wavelengths, so that we can constrain the temperature profile of the disk, and over a broad range of black hole masses and accretion rates. For the particular case of RXJ1131, we have programs to continue the X-ray monitoring of the system and to use $HST$ to monitor the ultraviolet flux ratios of the images. Obtaining a robust lower limit to the size of the X-ray emitting region may require denser sampling of the X-ray light curve. Measuring the mid-infrared flux ratios of the images would be the most important step toward rigorously imposing the relative macro magnifications with no offsets, as these would only be affected by the macro model and any large-scale gravitational perturbations (satellites).

We thank M. Dietrich, P. Osmer, B. Peterson, and R. Pogge for many discussions on quasar structure, and O. Blaes for his comments. We thank D. Sluse for providing estimates of the $R$-band line contamination in their VLT spectra of the system. The calculations in this paper were carried out on a Beowulf cluster obtained as part of the Cluster Ohio program of the Ohio Supercomputer Center. Support for this work at OSU was provided by NASA through Chandra Award GTO-07700072 and by the NSF through grant AST 0708082. The PSU portion of this work was supported by SAO contract SV4-74018.

Figure 6. Same as in Figure 4. This is a Case I example, so the magnification offsets are small but differ between the optical and X-ray data. It has a low stellar surface density ($f_* = 0.3$), a little smooth optical emission ($f_{\text{smooth}} = 0.2$), and the X-ray source is 28 times smaller than the optical. In the left panel, we find that the value of $f_*$ decreases with the model, while the half-light radius depends little on the model, with $R_{1/2} = 28$ (26) for a non-relativistic (relativistic) disk with a non-LTE (NLTE) atmospheric model, while the half-light radius depends little on the model, with $R_{1/2} = 114$ (117) for a non-relativistic (relativistic) disk radiating as a black body, and $R_{1/2} = 99$ (102) for a non-relativistic (relativistic) disk with a NLTE atmospheric model. Since the half-light radii are similar, the microlensing effects will be similar. In no case are the differences large enough to reconcile all the size estimates.
