Abstract

The next generation of bolometric experiments searching for rare events, in particular for the neutrino-less double beta decay, needs fast, high-sensitivity and easy-to-scale cryogenic light detectors. The CALDER project (2014-2020) developed a new technology for light detection at cryogenic temperature. In this paper we describe the achievements and the final prototype of this project, consisting of a $5 \times 5$ cm\textsuperscript{2}, 650 µm thick silicon substrate coupled to a single kinetic inductance detector made of a three-layer aluminum-titanium-aluminum. The baseline energy resolution is $34 \pm 1\text{(stat)} \pm 2\text{(syst)}$ eV RMS and the response time is 120 µs. These features, along with the natural multiplexing capability of kinetic inductance detectors, meet the requirements of future large-scale experiments.

1 Introduction

More than 60 years after their first detection by Cowan and Reines \cite{1}, the properties of neutrinos are still being investigated. Among them, the mass scale as well as their nature (Dirac or Majorana particle) are still unknown. If observed, a hypothesized nuclear process could unveil both of them: neutrino-less double beta decay (0νDBD) \cite{2,3}. 0νDBD is not allowed by the Standard Model since it violates the conservation of the B-L number \cite{4}. In this transition a nucleus decays emitting two electrons and no neutrinos, $(A,Z) \rightarrow (A,Z+2)+2\beta^−$, and the signal would consist of two electrons with a total kinetic energy equal to the Q-value of the transition. Current upper limits on the half-life of the decay are of the order of $10^{24} \text{−} 10^{26}$ yr, depending on the isotope under study \cite{5,6,7,8,9,10,11,12}.

Cryogenic calorimeters, historically also called “bolometers”, are among the leading technologies used to search for 0νDBD. The most sensitive experiment based on this technique, CUORE \cite{13}, is operating 988 TeO\textsubscript{2} cryogenic calorimeters of $\sim$750 g each with an average energy resolution of 7.8 ± 0.5 keV and a background index of $(1.49 \pm 0.04) \times 10^{-2}$ counts/(keV kg yr) in the energy region of interest \cite{14}. These performances allowed the CUORE experiment to set a 90\% C.I. Bayesian lower limit of $3.2 \times 10^{25}$ yr on the $^{130}$Te half-life for 0νDBD. The CUPID (CUORE Upgrade with Particle Identification) collaboration \cite{15} proposed a next generation 0νDBD experiment to upgrade the technique of CUORE, with the goal of decreasing the background by two orders of magnitude. CUPID will implement an active particle identification technique in order to identify and reject the dominant background source, i.e. α particles emitted by residual radioactive contamination in the materials facing the detectors \cite{16}.

In the first design, CUPID was based on TeO\textsubscript{2} cryogenic calorimeters, as in CUORE, complemented by cryogenic light detectors to detect the tiny amount of Cherenkov light ($\sim$100 eV) emitted only by β/γ interactions \cite{17}, thus enabling the background rejection. Nevertheless, the results obtained by CUPID-0 \cite{18,19,20,21,22} and CUPID-Mo \cite{19,23} experiments demonstrated that the α particles rejection capability can be
more easily achieved by using scintillating crystals like ZnSe (0νDBD of $^{82}$Se) and Li$_2$MoO$_4$ (0νDBD of $^{100}$Mo) in place of the TeO$_2$ ones because of their higher light signal compared with the Cherenkov yield. Furthermore $^{82}$Se and $^{100}$Mo benefit from a lower intrinsic background with respect to $^{130}$Te because their 0νDBD Q-value is above 2615 keV, where the $\beta/\gamma$ background contribution coming from natural radioactivity is greatly reduced. The CUPID group therefore decided to replace TeO$_2$ crystals in favour of ZnSe or Li$_2$MoO$_4$. Finally, because of the better radio-purity and energy resolution with respect to ZnSe, Li$_2$MoO$_4$ was chosen as crystal for CUPID.

It is clear from the previous considerations that the light detection technology will play a key role in the future of CUPID. To reach the background goal of $10^{-4}$ counts/ (keV kg yr), light detectors with small baseline fluctuations (< 100 eV RMS), good time resolution (better than 1 ms) and high reproducibility are needed. The light detectors of the first phase of the project will be based on the well established technology of germanium wafers equipped with Neutron Transmutation Doped Germanium (NTD-Ge) thermistors [24]. These sensors offer a typical baseline resolution of 50–60 eV RMS with rise time of 1–5 ms (see, e.g., Refs. [23, 25, 26] and references therein). A detector of 16 cm$^2$ in an optimized configuration reached an ultimate resolution of 20 eV RMS with rise time of 0.8 ms [27].

Nevertheless, the physics reach of CUPID (or other bolometric projects such as AMoRE [28]), could be largely increased with faster light detectors. Rise times of the order of hundreds of µs or below would allow to reject the ultimate envisioned background, consisting of pile-up events from the naturally occurring double-$\beta$ decay with the emission of 2 neutrinos [29, 30]. Furthermore, detectors offering multiplexing capabilities would allow to increase the number of devices without increasing the thermal load on the cryogenic facility, and ease of fabrication and low-cost readout are highly desirable features for large scale experiments. Apart from the limited time resolution, NTD sensors, being high-impedance devices, cannot be easily multiplexed at cryogenic temperatures.

Light detectors based on transition edge sensors (TES) have also been proposed as an alternative to NTDs for rare events searches [31] and demonstrated an extraordinary energy resolution down to 3.9 eV RMS with a distributed network of sensors [32]. Nevertheless, these devices cannot be easily scaled to thousands of channels because of their complex readout (based on SQUIDs) and limited reproducibility.

In this work we summarize the R&D and present the final results of the CALDER project, which developed an alternative technology to NTDs and TESs for the light detection based on Kinetic Inductance Detectors.

2 Kinetic Inductance Detectors with phonon mediation

In 2003 a new technology was proposed for the detection of electromagnetic radiation at cryogenic temperatures: the Kinetic Inductance Detectors (KIDs) [33]. A KID consist of a resonant LC circuit made of a superconducting metal operated well below its critical temperature $T_c$ (see the layout of the KID of CALDER in Fig. 1 left). The inductance $L$ is the sum of the magnetic inductance ($L_m$), which depends on the geometry of the inductor, and of the so called kinetic inductance ($L_k$), which depends on the density of Cooper pairs in the superconductor.

For common superconductors such as aluminium, the binding energy of the Cooper pairs is of the order of hundreds of µeV, so that even a tiny amount of absorbed energy can break a high number of Cooper pairs. The pair-breaking causes an increase of $L_k$ and of the surface resistance of the superconductor, $R$, resulting in a measurable change of the frequency ($\Delta f_0 = 1/2\pi\sqrt{LC}$) and the quality factor ($Q = f_0/\Delta f$) of the resonator (Fig. 1 right).

What makes KIDs interesting with respect to other cryogenic sensors is their natural multiplexing in the frequency domain. Indeed, hundreds of KIDs can be coupled to the same feedline, and can be simultane-
ously read by making them resonate at slightly different frequencies, which can be obtained by adjusting the layout of the capacitor and/or of the inductor of the circuit. This allowed to successfully operate very large arrays of KIDs, up to 1000. Despite these outstanding performances, their application in other fields could be limited by their small active surface (few mm²). However, Swenson et al. and Moore et al. showed that KIDs are also good phonon sensors: X-rays or, more in general, ionising radiation interacting in a substrate generate phonons that, through their scattering in the lattice, can eventually reach the KIDs, break the Cooper pairs and generate a signal. With the mediation of the phonons in the substrate it is therefore possible to increase the sensitive area beyond the KID dimensions, at the cost of a lower sensitivity due to inefficiencies in phonon transmission and absorption in the KID.

3 The 4 and 25 cm² light detectors of CALDER

The CALDER (Cryogenic wide-Area Light Detectors with Excellent Resolution) project developed large area cryogenic light detectors based on KIDs exploiting the phonon-mediation. The first prototypes were made depositing 4 multiplexed aluminum resonators on a 2 × 2 cm², 300 µm thick silicon substrate (Fig. 2 left) and reached an energy resolution of 150 eV RMS. Then we improved the layout of the LC circuit in order to increase its area for a better phonon collection (from 2.4 to 4 mm²) and in order to increase the quality factor of the resonator (from 15000 to 150000), which in turn needed also an improvement of the quality and accuracy of the metal deposition. Good results were obtained, both in terms of energy resolution and rise time (80 eV and 10 µs respectively) and also in wide range of operating temperatures (10 − 200 mK).

A similar prototype was successfully used as cryogenic light detector coupled to a 2 × 2 × 2 cm³ Li₂MoO₄, demonstrating very promising performances.

In order to further improve the energy resolution, we moved the R&D to KIDs made of superconductors more sensitive than aluminum. Indeed, the sensitivity depends strongly on the kinetic inductance of the silicon, to ensure an efficient phonon transmission and absorption in the KID. We started testing several resonators made of sub-stoichiometric titanium nitride without obtaining satisfactory results, mainly because of the poor reproducibility of the film, a difficulty encountered also by other groups. We then moved to granular aluminum that, because of its tunable energy gap and large fraction of kinetic inductance, is a promising material in applications for quantum circuits. Nevertheless, we were not able to reach a baseline resolution better than ~150 eV, likely because of the acoustic mismatch between granular aluminum and silicon, that prevents an efficient collection of phonons. On the contrary, multi-layers of aluminum and titanium showed from the beginning very promising results, thanks to the higher kinetic inductance of titanium. We tested several bi-layers consisting of titanium and aluminum with variable thickness. The best baseline resolution, 50 eV RMS, was obtained with 10 nm of titanium and 25 nm of aluminum. A further improvement was achieved moving from a bi-layer to a tri-layer of aluminum-titanium-aluminum, in order to enhance the acoustic match between KID and silicon. The best performance was obtained with a three-layer (14 nm Al, 33 nm Ti, 30 nm Al) that, thanks to a 8 times higher kinetic inductance than aluminum, allowed a very competitive baseline energy resolution of 26 eV RMS.

The last step of the project consisting in the scale-up of the Si substrate to the final size of 5 × 5 cm². Such dimensions were chosen at the beginning of the CALDER R&D activity to match the size of the faces of the TeO₂ crystals of CUORE, in order to maximize the light collection efficiency. Scaling the substrate surface from 2×2 to 5×5 cm², and at the same time preserving the baseline resolution, turned out to be the most complex technological challenge. Even if we used the same KID design tested in previous detectors, we had to build and test tens of different prototypes before obtaining a comparable quality factor of the resonator. The reason behind this problem turned out to be the CPW feed line. Indeed, in order to decrease the number of phonons absorbed by non sensitive Al regions its width was only 85 µm. At the same time, in order to collect as many phonons as possible, we increased the number of KIDs from 1 to 4, with the feedline running through the whole substrate and being 6 times longer than in the
Fig. 3: Rendering of the shielding pot anchored to the 20 mK plate of the cryostat at the top. The pot consists of three concentric layers acting as magnetic and radiation shields. The outer one is made of Cryophy® for magnetic shielding, the middle one of copper for thermalization, and the inner one of aluminum for further magnetic and radiation shielding. The mechanical design of the parts constituting the assembly has been carried out considering the effect of the differential thermal contractions related to the different materials constituting the system (copper, aluminum and Cryophy®). In this way, at cryogenic temperatures, the system has maintained minimum gaps without introducing unwanted mechanical stress on the components. The “chimneys” are feedthroughs for cables made of Cryophy® as well.

The optical fiber, shown in yellow, illuminates the detector from the top and is connected on the other end to a room temperature LED (not shown in the figure). The detector frame is anchored to the copper shield with two copper bars for thermalization.

$2 \times 2 \text{ cm}^2$ detector. This caused impedance mismatches that reduced by more than an order of magnitude the quality factor. This effect was not visible in EM simulations and therefore we proceeded by trials and errors. In the end the simplest solution turned out also to be the most reliable and high-performing: we minimized the feedline length by making it straight from one side of the wafer to the opposite one (5 cm), and coupled to it a single KID. Figure 2 (right) shows the final detector held in a copper frame by PTFE washers consisting in a $5 \times 5 \text{ cm}^2$, 650 µm thick Si wafer monitored by an AlTiAl (14 nm, 33 nm, 30 nm) three-layer resonator with the same geometry showed in Fig. 1 left.

Fig. 4: Triggered 1.3 keV signal in the phase (red) and amplitude (blue) directions.

4 Measurement set-up

The device was anchored to the coldest point of a dry $^{3}$He/$^{4}$He dilution refrigerator and cooled down to 20 mK. The outside vessel of the refrigerator was surrounded by a µ-metal cylinder shield in order to reduced the magnetic field at the sample location. Finally, to prevent that both the residual magnetic field inside the cryostat and the thermal radiation from the 600 mK stage spoiled the resonator quality factor, the detector holder was placed inside a shielding pot consisting in a three layers of Cryophy® copper and aluminum (Fig. 3).

An optical fiber of 600 µm core diameter was placed on the top of the pot and illuminated the Si substrate from a distance of 13.6 cm. The opposite end of the fiber was connected to a 400 nm LED lamp located at room temperature outside the refrigerator. Given the numerical aperture of the fiber of 0.22 and the distance from the Si surface, photons illuminate the entire 5x5 cm² surface, thus simulating the crystal scintillation light. A $^{55}$Fe X-ray source was faced to a corner of the Si substrate, on the opposite position with the respect to the KID and the feedline.

The resonator was excited and probed at the resonant frequency, $f_0 = 2.333 \text{ GHz}$. The output signals were fed into a CITLF3 SiGe cryogenic low noise amplifier installed at the 4 K stage of the cryostat, downconverted at room temperature using a superheterodyne electronics and then digitized at a sampling frequency of 500 kSPS. Time traces up to 12 ms long of the real (I) and imaginary (Q) parts of the transmission $S_{21}$ were acquired with a software trigger. Finally the I and Q waveforms were converted into phase and amplitude variations relative to the center of the resonance loop. Figure 4 shows a signal produced by 1

1 Oxford Instruments, Dry Dilution Refrigerator Triton 200.
an energy deposition of 1.3 keV in the Si wafer, which is similar to the light signal expected from the 0ν-DBD of $^{100}$Mo. The average rise time of the signals is 120 µs, dominated by the phonon propagation in the substrate, while the decay time is 550 µs, dominated by the recombination of the Cooper pairs [52]. For the estimation of the signal amplitude, the phase and amplitude waveforms are combined with a bi-dimensional matched filter to maximize the signal to noise ratio [44].

5 Results

We used the LED lamp to shine different amount of photons and to perform an absolute energy calibration of the detector [49]. The lamp is controlled with an external trigger that we fire at increasing rate in order to increase the number of photons in a burst. The photon bursts are much shorter than the rise time of the signal, at maximum 2 µs long, and are therefore seen as a δ(t) from the KID. Each burst is composed by N photons of same energy (400 nm, corresponding to 3.1 eV) reaching the Si wafer and absorbed by it. We denote the average number of absorbed photons by $<N>$. This process follows the Poisson statistics and therefore the standard deviation is $\sqrt{<N>}$. As shown in Fig. 5, for each optical burst, the distribution of the amplitude of the signals is well described by a Gaussian with a standard deviation $\sigma$. The predicted trend of $\sigma$ as a function of the mean Amplitude ($<\text{Amplitude}>$) can be written as the combination of two uncorrelated terms that can be added quadratically, i.e. the poissonian component and the baseline noise energy resolution:

$$\text{Energy} = a \text{ pulses} + b \text{ pulses}$$

$$\sigma = \sqrt{\sigma_0^2 + R \cdot E_p \cdot <\text{Amplitude}>}$$

where $\sigma_0$ is the baseline noise energy resolution, R the energy calibration coefficient and $E_p$ the photon energy. The $\sigma$ vs $<\text{Amplitude}>$ trend is well described by Eq. 1 as shown in Fig. 5middle and allowed us to extract the calibration coefficient R = 18.59±0.83 mrad/keV.

Finally, the bottom panel of the figure shows the calibrated energy as a function of the number of lamp triggers.

After calibration the baseline noise energy resolution is 90 eV, a value obtained with the pulse-tube cryocooler on and without any decoupling system to reduce vibrations (see e.g. Ref [53]). These represent the least favorable configuration, since it is well known that the mechanical vibrations induced by dry refrigerators increase the noise of cryogenic detectors. NTDs and TES detectors, at least in the applications for rare events

6 Conclusion

In this paper we described the technological challenges and solutions in the development of wide-area cryogenic light detectors based on Kinetic Inductance Detectors. We presented the final prototype of the CALDER project, a single KID made of a tri-layer aluminum-titanium-aluminum deposited on a 5×5 cm² Silicon substrate acting as light absorber.

This light detector features a rise time of 120 µs and a vibration-limited noise resolution of 90 eV RMS, matching the requirements of next-generation experiments. We proved that the energy resolution is not limited by the detector itself, rather by the vibrations induced by the pulse-tube cryocooler. In absence of such vibrations (e.g. in fridges such as the CUORE cryostat featuring an active noise cancellation or implementing a decoupling system for the pulse-tube) the energy resolution improve to 34 eV RMS.

Compared to the baseline technology of CUPID, the presented device has a similar energy resolution and an order of magnitude faster response time, a key parameter for background suppression. Finally, it offers ease in multiplexing and simple fabrication, important aspects for experiments with thousands of channels.
