Abstract

RR Telescopii (RR Tel) is an interacting binary system in which a hot white dwarf (WD) accretes matter from a Mira-type variable star via gravitational capture of its stellar wind. This symbiotic nova shows intense Raman-scattered O VI features at 6825 and 7082 Å. We present high-resolution optical spectra of RR Tel taken in 2016 and 2017 with the Magellan Inamori Kyocera Echelle (MIKE) spectograph at the Magellan-Clay telescope, Chile. We aim to study the stellar wind accretion in RR Tel from the profile analysis of Raman O VI features. With an asymmetric O VI disk model, we derive a representative Keplerian speed of $>35 \text{ km s}^{-1}$, and the corresponding scale $<0.8 \text{ au}$. The best fit for the Raman profiles is obtained with a mass-loss rate of the Mira $M \sim 2 \times 10^{-6} \text{ M}_\odot \text{ yr}^{-1}$ and a wind terminal velocity $v_{\infty} \sim 20 \text{ km s}^{-1}$. We compare the MIKE data with an archival spectrum taken in 2003 with the Fiber-fed Extended Range Optical Spectrograph at the MPG/ESO 2.2 m telescope. It allows us to highlight the profile variation of the Raman O VI features, indicative of a change in the density distribution of the O VI disk in the last two decades. We also report the detection of O VI recombination lines at 3811 and 3834 Å, which are blended with other emission lines. Our profile decomposition suggests that the recombination of O VII takes place nearer to the WD than the O VI 1032 and 1038 emission region.

1. Introduction

Symbiotic stars are interacting binary systems consisting of an evolved giant transferring mass to a hot compact object, in most cases a white dwarf (WD); e.g., Kenyon 1986. In the general case, it is believed that the accretion occurs via the stellar wind from the primary, known as Bondi–Hoyle–Lyttleton (BHL) wind accretion. For the D-type (dust) symbiotic stars, the widest binary systems composing of a Mira-type variable, several hydrodynamical simulations suggest a new mass-transfer model based on Bondi–Hoyle–Lyttleton (BHL) wind accretion. For the D-type (dust) symbiotic stars, the widest binary systems composing of a Mira-type variable, several hydrodynamical simulations suggest a new mass-transfer model based on Bondi–Hoyle–Lyttleton (BHL) wind accretion. The mass-transfer rate is obtained from observations of the BHL wind accretion. This lends support to the suggestion that D-type symbiotic stars are promising candidates of type Ia supernova progenitors (e.g., Ilickiewicz et al. 2019).

RR Telescopii (RR Tel) is a dusty-type symbiotic nova comprising a Mira component and a WD. A nova-like outburst occurred in 1944 when RR Tel brightened by $\sim$7 mag in the visual band (Mayall 1949). In 1949, the extended atmosphere started to shrink and entered a nebular phase. Subsequently, its luminosity has been slowly fading for several decades (e.g., Mürset et al. 1991; Nussbaumer & Dumm 1997). A recent light curve from the ASAS-SN photometric database shows that the overall $V$ magnitude is still in a trend of steady decline. It changed from 11.7 to 11.9 during the last four years (Shappee et al. 2014; Kochanek et al. 2017). Meanwhile, the effective temperature of the WD has continued to rise from $T \sim 6750$ K in 1949 May (Pottasch & Varsavsky 1960) and it has exceeded $>140,000$ K after 1978 (e.g., Jordan et al. 1994; Hayes & Nussbaumer 1996). Based on the recent X-ray observations with XMM-Newton, González-Riestra et al. (2013) estimated its temperature $T \sim 154,000$ K and luminosity $L \sim 5000 L_\odot$, assuming a distance of 2.6 kpc. The orbital period of this object is still quite uncertain but it is believed to exceed several decades (Lee & Park 1999; Schmid & Schild 2002).

From time-series spectroscopic observations of RR Tel between 1950 and 1960, Thackeray & Webster (1974) reported a strong, unidentified emission band at 6825 Å having a broad width of $\sim 30$ Å with a double-peak profile. They noted that whenever the 6825 band appeared, the rest of the spectrum showed lines of high ionization, which implied that the origin of the band is related to high-ionized species. A second, weaker band at 7082 Å was also detected, whose profile bears a striking similarity to the 6825 feature (Allen 1979). Because of their observational properties, including abnormally broad width and the double-peak profile, Allen (1979) proposed that both emissions come from the same atomic or molecular species.

The identification of the two bands was made by Schmid (1989), who proposed that the two broad bands at 6825 Å and 7082 Å are due to the Raman scattering of O VI $\lambda 1032$ and 1038 doublet by atomic hydrogen $H_1$. Synchronous far-UV and optical observations for symbiotic stars including RR Tel provided support for his identification of the Raman O VI features (Espey et al. 1995; Birriel et al. 2000). In this scattering process, an O VI 1032 photon is incident on $H_1$ in the ground state, and de-excitation into 2$s$ state produces an
optical Raman-scattered photon with $\lambda = 6825 \text{ Å}$. A similar process with an O VI 1038 photon results in an optical photon at 7082 Å. Figure 1 shows the scattering process in the symbiotic star. The heterogeneous environment in symbiotic binaries includes the nebular region photoionized by intense far-UV radiation from the hot source and the dense neutral region around the donor star, providing an excellent laboratory to study Raman scattering by H I (e.g., Nussbaumer et al. 1989; Schmid 1989).

The inelasticity of Raman scattering requires that the wavelength of an emergent Raman photon is almost solely determined by the relative motion between the far-UV O VI emission region and the H I scattering region and negligibly dependent on the observer’s line of sight. This unique property allows us to investigate the mass-transfer process with an edge-on view of the cool star. Follow-up spectropolarimetric observations revealed that the Raman O VI bands of RR Tel are strongly polarized and show complicated line structures with a polarization flip in the red wing (Schmid & Schild 1994; Harries & Howarth 1996; Schmid et al. 1999). The spectropolarimetric properties were explained by a very extended scattering region responsible for a large mass-loss rate. Another model was suggested by Lee & Park (1999), who adopted an accretion disk around a WD with an asymmetric matter distribution, resulting in the asymmetric double-peak profiles of the Raman O VI in RR Tel. Previous studies on line formation of Raman O VI features in other symbiotic stars show that their profiles provide valuable kinematic information on the accretion disk. In particular, the main peak separation of Raman O VI features indicates a representative velocity scale $\sim 50 \text{ km s}^{-1}$ of the accretion disk around the WD (e.g., Lee & Kang 2007; Heo & Lee 2015; Heo et al. 2016).

Additionally, an interesting point regarding Raman O VI is that the two profiles, as usual, are not identical in a given object, even though the O VI $\lambda \lambda 1032$ and 1038 photons are formed in the same region. The difference in flux between the two peaks is more evident in the 7082 feature than the 6825 profile. O VI $\lambda \lambda 1032$ and 1038 resonance doublet lines arise from $2s_{1/2} - 2p_{3/2,1/2}$ transitions. Since the oscillator strength of the $2s_{1/2} - 2p_{3/2}$ transition is twice larger than that of the $2s_{1/2} - 2p_{1/2}$ transition, it is expected that the flux ratio $F(1032)/F(1038) = 2$, in the optically thin region. In accordance with the ratio of oscillator strength, O VI 1032 is twice more optically thick than O VI 1038, $\tau(1032) = 2\tau(1038)$, which makes it more difficult for an O VI $\lambda 1032$ line photon to escape from the site. We, therefore, expect that the flux ratio $F(1032)/F(1038)$ may deviate from the optically thin limit of 2 and approach unity in an optically very thick medium. Heo & Lee (2015) adopted the local variation of the flux ratio $F(1032)/F(1038)$ in the accretion disk to account for the profile disparity of the Raman O VI features in a symbiotic nova V1016 Cyg. As demonstrated by these results, Raman O VI features can be an ideal spectroscopic tool to investigate the vicinity of the WD and further probe the mass-transfer process associated with stellar wind accretion in symbiotic stars.

Although RR Tel is a well-studied symbiotic nova, there has been a lack of optical studies for the past two decades. The most recent observation in the literature was conducted in 2000, analyzed by Young (2012). In this paper, we present and discuss our high-resolution spectroscopic observations of the
Raman O VI features in RR Tel, conducted in 2016 and 2017 using the Magellan Inamori Kyocera Echelle (MIKE) spectrograph installed on the 6.5 m Magellan-Clay telescope, Chile. In Section 2, we investigate the Raman O VI features comparing the archival far-UV data taken in 2002 with the Far-Ultraviolet Spectroscopic Explorer (FUSE) satellite and the almost contemporary optical spectrum taken in 2003 with the Fibre-fed Extended Range Optical Spectrograph (FEROS) at the MPG/ESO 2.2 m telescope. A detailed profile analysis of the Raman O VI features based on the accretion disk model was performed, and the results are shown in Section 3. Our finding of the O VI λ 3811 and 3834 doublets from our profile decomposition is described in Section 4. Discussion and summary follow in Sections 5 and 6.

2. Observations

2.1. MIKE Spectrum

We obtained high-resolution optical spectra of RR Tel using the MIKE spectrograph (Bernstein et al. 2003). The double echelle spectrograph MIKE covers the wavelength range of 3350-5000 Å (blue) and 4900-9500 Å (red) in its normal configuration. A slit width of 0.9×5.9 was used, resulting in resolving power \( R \approx 27,000 \) and \( \approx 35,500 \) on the blue and red sides, respectively. To increase the signal-to-noise ratio \( (S/N) \), a 2×2 binning was applied in both the spectral and spatial directions. Observations were carried out on 2016 July 30 and 2017 July 26, for total exposure times of 2000 s and 2400 s, respectively. With these integration times, the spectra have significant \( S/N > 100 \) for strong lines suitable for profile analysis. ThAr spectra were taken for wavelength calibration.

We reduced the MIKE data using the Carnegie Python Distribution (CarPy) pipeline (Kelson et al. 2000; Kelson 2003) and NOAO.ondespec package of the Image Reduction and Analysis Facility (IRAF).\(^9\) The data are overscan-corrected, bias-subtracted, extracted, wavelength calibrated, and flat-fielded with quartz lamps within the pipeline. Individual exposures were then combined using the IRAF task scombine.\(^5\) Due to the poor weather conditions on the night of 2016 July 30, flux calibration was not possible. For the observing night 2017 July 26, we observed the spectrophotometric standard star HR 7950 under the photometric condition. Flux calibration was performed with the IRAF tasks standard, sensfunc, and calibrate.

The left and right panels of Figure 2 show the Raman-scattered O VI features at 6825 and 7082 Å. To make quantitative profile comparisons of the two Raman O VI features, we transform the observed wavelengths into the O VI Doppler factor \( \Delta V_{\text{atomic}} \) computed in the parent far-UV O VI space. The 2003 and 2016 spectra are multiplied by an artificial factor for profile comparison with the flux-calibrated 2017 data.

\[ \chi^2 = \frac{1}{\text{Total Exposure Time}} \times \frac{\text{Counts}}{2} \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1} \text{Å}^{-1} \]

\[ \chi^2 = \frac{1}{\text{Total Exposure Time}} \times \frac{\text{Counts}}{2} \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1} \text{Å}^{-1} \]

\[ \chi^2 = \frac{1}{\text{Total Exposure Time}} \times \frac{\text{Counts}}{2} \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1} \text{Å}^{-1} \]

\[ \chi^2 = \frac{1}{\text{Total Exposure Time}} \times \frac{\text{Counts}}{2} \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1} \text{Å}^{-1} \]

\[ \chi^2 = \frac{1}{\text{Total Exposure Time}} \times \frac{\text{Counts}}{2} \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1} \text{Å}^{-1} \]
pulsation of Mira, whereas the near-IR light curves show a clear periodicity (Gromadzki et al. 2009).

To measure the total line fluxes for the Raman O VI features, we assume that the emission having the Doppler factor $\Delta V_{\text{atomic}}$ between $-60 \text{ km s}^{-1}$ and $100 \text{ km s}^{-1}$ is a Raman O VI feature. In these regions, the contributions of other spectral lines, including TiO or VO absorption lines from the Mira and telluric lines, are negligible. There is a telluric O$_2$–B band between 6870 and 6950 Å, but not affecting both Raman O VI features (Groppi & Hanson 1996). A few unknown emission lines with FWHM $<0.5$ Å are also detected at the wavelength range of Raman O VI features. However, their contribution to the total line fluxes are negligible due to the relatively small intensities compared with the Raman features. Therefore we obtain the total line fluxes of the Raman O VI features $F(6825) = (30.34 \pm 0.11) \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$ and $F(7082) = (5.98 \pm 0.08) \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$ for the 2017 data.

The Raman line fluxes of RR Tel were studied in previous observations between 1993 and 1996 (e.g., Espey et al. 1995; Crawford et al. 1999; Schmid et al. 1999). A steady decrease was found over the period, and the same behavior is shown for the far-UV O VI 1032 and 1038 emissions. We note that the fluxes of both Raman O VI in the MIKE data have decreased by about 30% from 1996 October. The measurements are summarized in Table 1. The decrease in the line intensity is consistent with the trend of general slow fading started in 1949 after its outburst (e.g., Nussbaumer & Dumm 1997; Contini & Formiggini 1999).

### Figure 3

Part of the MIKE spectrum of RR Tel around Raman-scattered O VI features at 6825 and 7082 Å taken in 2017 July. This region has a constant continuum value of $2.0 \times 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1} \text{ Å}^{-1}$, which is not contaminated by the Mira component. The Raman O VI features are located away from the telluric bands at 6870 Å.

### Figure 4

Part of the FUSE spectrum of RR Tel around O VI λλ 1032 and 1038 taken in June 2002. The light gray line represents the raw data, whereas the black line shows the binned spectrum.

#### 2.2. FUSE Spectrum

RR Tel was observed on 2002 June 14, with the FUSE satellite as part of the Cycle 3 program C141 (data ID: C1410102000; PI: P.R. Young). The FUSE spectrum of RR Tel was taken for an exposure time of 128 s through the low-resolution aperture (LWRS: 30$^\prime \times 30^\prime$) using TTAG (Photon Address) mode. The SiC2 channel covers a wavelength range of 917–1104 Å at a spectral resolution of 12,000–20,000 (Moos et al. 2000; Sahnow et al. 2000). The data were reprocessed and archived at MAST with the CalFUSE pipeline version 3.2.1. The extracted data is binned in wavelength with a bin size of 0.013 Å (Dixon et al. 2007). Considering that the observation was made under the low-resolution mode, we binned the data by a spectral resolution of 0.362 Å.

In Figure 4, we present a zoom-in of the FUSE spectrum centered on the two strongest emission lines, O VI 1032 and 1038. The light gray line represents the raw data, whereas the black line shows the binned spectrum. The O VI emissions have line fluxes of $F(1032) = (2.01 \pm 0.56) \times 10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$ and $F(1038) = (1.18 \pm 0.32) \times 10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$, respectively, yielding the flux ratio of $F(1032)/F(1038) = 1.70$. There has been a steady decrease in line fluxes of both O VI emissions from $F(1032) = 2.56 \times 10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$ and $F(1038) = 1.54 \times 10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$ in 1993 (Schmid et al. 1999)—a drop of 22%. We summarize the observed values of O VI lines and compare them with previous measurements from other research works in Table 2. We note that the flux ratio $F(1032)/F(1038)$ has remained almost constant at $\sim 1.7$ throughout this period.
2.3. FEROS Spectrum

RR Tel was observed with FEROS installed on the MPG/ESO 2.2 m telescope for a total exposure time of 600 s on 2003 November 13. The spectrum spans the wavelength region 3527–9216 Å and has a spectral resolution of $R \sim 48,000$ (Kaufer et al. 1999). The data were reduced automatically using the FEROS Data Reduction Software (DRS) pipeline version fern/1.0 and archived at the European Southern Observatory (ESO) database.8 The data are overscan-corrected, bias-subtracted, extracted, and flat-fielded. The extracted, flat-fielded data are wavelength calibrated and rebinned in wavelength with a bin size of 0.3 Å. The reduced spectra are not flux calibrated.9 In Figure 2, the light gray lines correspond to the FEROS data. Not being flux calibrated, the FEROS data is multiplied by an artificial factor to compare their profiles with that of the flux-calibrated MIKE data.

Following the same method used for the MIKE data, we measure the center of the strong emission lines (He I λ7065 and λ6678, [O III] λ5007 and λ4959), and obtain the systemic velocity $v_{\text{sys}}$ of $-59.7$ km s$^{-1}$. Through two-component Gaussian modeling of the Raman features, we find that the two peaks of the Raman O VI 6825 Å are $\lambda_{\text{blue}} = 6822.75$ Å and $\lambda_{\text{red}} = 6829.75$ Å. These correspond to a Doppler factor of $V_{\text{blue}} = -10.0$ km s$^{-1}$ and $V_{\text{red}} = 36.5$ km s$^{-1}$ resulting in the peak separation $\Delta V = 46.5$ km s$^{-1}$. For the Raman O VI 7082 Å, the peak separation $\Delta V = 48.5$ km s$^{-1}$ is obtained. We summarize the Gaussian fitting parameters for the Raman features in Table 3.

2.4. Profile Variation of Raman O VI

In previous studies, it was found that the Raman O VI features of RR Tel show an asymmetric double-peaked profile, where the red peak is stronger than the blue one (e.g., Allen 1980; Schmid et al. 1999). Harries & Howarth (1996) investigated the temporal variation of the Raman O VI 6825 feature between 1992 and 1994, from which they found a slight decrease in (normalized) line intensity while the overall profiles remained unchanged (see Figure 8(d) in Harries & Howarth 1996).

By comparing the data obtained in the years of 2003, 2016, and 2017, we find that both Raman O VI profiles show significant variations. In Figure 2, we overplot the FEROS spectrum taken in 2003 and the MIKE data observed in 2016 and 2017. It is obvious that the asymmetry of both Raman profiles has grown over the last two decades, whereas there is no significant change between 2016 and 2017. To describe the profile asymmetry in a given Raman feature, we use parameter $f_{\text{red}}/f_{\text{blue}}$, the ratio between the peak values of the two Gaussian components. We find that the asymmetry parameter $f_{\text{red}}/f_{\text{blue}}$ of Raman O VI 6825 increased 26% from 1.94 in 2003 to 2.45 in 2016. This change is even more apparent in the 7082 feature, a 43% increase from 3.94 in 2003 to 5.65 in 2016.

3. Line Formation of Raman O VI

We introduce our line formation modeling via a Monte Carlo approach to compute the flux and the profiles of Raman-scattered O VI features. The Monte Carlo simulation starts with a generation of a far-UV O VI photon at a random place in an accretion disk. The O VI photon enters the H I region where it is Rayleigh scattered. It escapes the region if the photon has an optical depth $\tau$ larger than $\tau_{\infty}$, the scattering optical depth to an observer at infinity, or becomes an optical photon through Raman scattering. A full description of the simulations, including the escape condition and the scattering process, can be found in Lee & Lee (1997).

It is worth noting once again that the line profiles of Raman-scattered features are almost independent of the observer’s line of sight and are almost solely determined by the relative motion between the far-UV O VI emission region and the H I scattering region. Because the H I region around the Mira commands an

almost perfect edge-on view of the accretion around the WD, the profile analysis of Raman-scattered features provides crucial information, including physical extent, density distribution, and kinematics of the OVI 1032 and 1038 emission region around the WD (Lee & Kang 2007; Heo et al. 2016; Lee et al. 2019).

3.1. Stellar Wind and the STB Ionization Front

First of all, to model the density distribution of H I around the Mira, it is assumed that the stellar wind from the Mira follows a beta law, where the radial wind velocity \( v_r(r) \) is given by

\[
v_r(r) = v_\infty (1 - R_*/r)^\beta.
\]  

(1)

Here, \( R_* \) is the launching site of the wind and \( v_\infty \) is the wind terminal velocity (e.g., Lamers & Cassinelli 1999). We choose the parameter \( \beta = 1 \) for simplicity in our Monte Carlo simulations.

The slow stellar wind around the Mira is illuminated by intense far-UV radiation from the hot component, and hence some parts facing the WD are photoionized. Sequist et al. (1984) presented their photoionization calculation to find the ionization front, known as the STB model. In the STB model, the ionization front in the stellar wind region is determined by the balance of photoionization rate by the H-ionizing luminosity from the hot component and recombination rate set by the mass-loss rate.

In the STB geometry, the ionization front is specified by the ionization parameter \( X \), which is given by

\[
X = \frac{4\pi a L_H}{\alpha_B (m_H v_\infty)^2}.
\]  

(2)

Here, \( a \) is the binary separation, \( L_H \) is the H-ionizing photon number luminosity, \( \alpha_B \) is the case B recombination coefficient for H I, and \( m_H \) is the proton mass. In this work, we adopt the values of \( a = 56 \) au and \( L_H = 7 \times 10^{47} \) s\(^{-1}\) that were used in previous works (González-Riestra et al. 2013; Hinkle et al. 2013).

3.2. An Asymmetric O VI Accretion Disk

Many hydrodynamical simulations of stellar wind accretion in detached binaries involving an evolved giant star show that stable disks can form around WD (e.g., Mastrodemos & Morris 1998; de Val-Borro et al. 2009; Huarte-Espinoza et al. 2013). In view of the fact that the Raman O VI profiles are dependent exclusively on the relative motion between the emitter and scatterer, the double-peak profiles of Raman O VI strongly imply that the far-UV O VI emission lines are formed in regions that move toward the H I region and recede from it. In this work, the far-UV O VI 1032 and 1038 emission regions are identified as part of the accretion disk formed around the WD. Since Raman O VI profiles reflect only relative kinematics between the O VI emission region and the H I scattering region, but not the radial motion nor 3D distribution, a simple circular disk at \( z = 0 \) is used in our simulation. We also assume that the disk follows a Keplerian velocity profile. Our assumption is supported by hydrodynamical simulations, which show that the orbital speed in the disk is close to Keplerian (e.g., de Val-Borro et al. 2009).

Wind accretion can lead to an asymmetry of the accretion flow around WD with significant density enhancement of the entering side, associated with flow streamlines, bow shocks, ellipticity, etc. (e.g., de Val-Borro et al. 2009; Huarte-Espinoza et al. 2013; Saladino et al. 2018). We, therefore, attribute the red peak enhanced Raman O VI profiles to the asymmetry of the matter distribution in the O VI disk (e.g., Heo & Lee 2015). The part of the accretion disk on the entering side is moving away from the Mira and hence is characterized by positive Doppler factors for Raman-scattered O VI: we call this region the red emission region (RER) and the opposite side the blue emission region (BER).

It is noteworthy that the profiles of the two Raman O VI features are not identical: specifically, the ratio of the red and blue peak fluxes \( f_{\text{red}}/f_{\text{blue}} \) is 2.4 for the Raman 6825 whereas it is 5.8 for the Raman 7082 as shown in Section 2.4. The disparate profiles of the two Raman O VI features can be explained by the local variation of the ratio \( F(1032)/F(1038) \) in the O VI emission region, which decreases from 2 to 1 as optical depth increases (Heo & Lee 2015). The BER, assumed to be of high density, is characterized by the flux ratio \( F(1032)/F(1038) \sim 1 \), whereas the BER is much more sparse, resulting in \( F(1032)/F(1038) \sim 2 \).

3.3. Monte Carlo Results

To reproduce the peak separation of the Raman O VI features, the Keplerian velocity is set to \( >35 \) km s\(^{-1}\). It corresponds to the physical size of \( <0.8 \) au when we adopt \( M_{WD} = 0.65 M_\odot \) as the mass of the WD (González-Riestra et al. 2013). The asymmetry of the matter distribution in the accretion disk is given as a function of the azimuthal angle \( \theta \) measured from the line toward the Mira. The best fit is made using the following density function,

\[
n(\theta) = n_0(1 + \theta \times (2\pi - \theta)^\beta)/8500.
\]  

(3)

In Figure 5, we present the schematic top view of the O VI disk with the corresponding O VI emissivity (left). In the right panel, the solid line represents the O VI density profile \( n(\theta)/n_0 \) as a function of \( \theta \). The O VI emissivity is dominant in the RER \( (0 < \theta < \pi) \), whose peak is at around \( \theta = 0.3\pi \).

Considering the disparate profiles of the two Raman O VI, we use the flux ratio \( F(1032)/F(1038) \), varying from 1.5 to 2, as a function of \( \theta \)

\[
F(1032)/F(1038) = 2 - \theta \times (2\pi - \theta)^4/1500,
\]  

(4)

which is schematically illustrated in the middle panel and represented by the dotted line in the right panel of Figure 5.

Adopting the asymmetric O VI accretion disk model supplemented by the locally varying \( F(1032)/F(1038) \), Monte Carlo simulations were carried out under various parameters, a mass-loss rate \( \dot{M} \) ranging from \( 1 \times 10^{-6} \) to \( 1 \times 10^{-5} M_\odot \) yr\(^{-1}\) with a step width of \( 1 \times 10^{-6} M_\odot \) yr\(^{-1}\) and terminal velocities of the Mira wind \( v_\infty \) with 10, 15, 20, and 25 km s\(^{-1}\). These parameter sets give the ionization parameter \( X \) from 0.2 to 80.

We find that the double-peak structure of Raman O VI features in RR Tel is diluted if the stellar wind velocity exceeds \( v_\infty > 20 \) km s\(^{-1}\) or the ionization parameter \( X < 1.25 \). With the maximum velocity of \( v_\infty = 20 \) km s\(^{-1}\), we, therefore, constrain \( \dot{M} < 8 \times 10^{-6} M_\odot \) yr\(^{-1}\), which gives \( X \sim 1.25 \). The corresponding ionization front is presented in Figure 1. The best-fit result is obtained with \( v_\infty \sim 20 \) km s\(^{-1}\) and \( \dot{M} \sim 2 \times 10^{-6} M_\odot \) yr\(^{-1}\).
In Figure 6, we present our best-fit profiles for the Raman O VI features. The black lines show the MIKE data, while the light gray lines represent the results of our simulations.

Raman scattering efficiency, $\eta$, is defined as the number ratio $N_{\text{FUV}}$ (FUV)/$N_{\text{Raman}}$ of the incident and Raman-scattered photons. The conversion rate for Raman-scattered O VI features was derived from direct measurement of the O VI far-UV emissions in far-UV spectra and O VI Raman features in optical spectra (Schmid et al. 1999; Birriel et al. 2000). Those authors suggested that $N_{6825}/N_{1032}\sim 6\%$ and $N_{7082}/N_{1038}\sim 2\%$, respectively. From our Monte Carlo simulations, we obtained 10.5% for the $\lambda 1032 \rightarrow \lambda 6825$ conversion and 4.3% for $\lambda 1038 \rightarrow \lambda 7082$ conversion, respectively.

For our best-fit results, we obtain the total line flux $F(6825) = 3.0 \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1}$ and $F(7082) = 0.7 \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1}$, respectively. Adopting a distance of 2.6 kpc (Whitelock 1988; González-Riestra et al. 2013), the corresponding number luminosities of Raman-scattered photons emitted per unit time are $N_{6825} = 5.6 \times 10^{45} \text{ s}^{-1}$ and $N_{7082} = 1.3 \times 10^{45} \text{ s}^{-1}$. Taking the conversion efficiency for O VI, we deduce the far-UV number flux densities $N_{1032} = 5.3 \times 10^{46} \text{ s}^{-1}$ and $N_{1038} = 3.1 \times 10^{46} \text{ s}^{-1}$. The corresponding line fluxes are obtained $F(1032) = 1.3 \times 10^{-9} \text{ erg cm}^{-2} \text{s}^{-1}$ and $F(1038) = 7.3 \times 10^{-10} \text{ erg cm}^{-2} \text{s}^{-1}$, yielding the flux ratio $F(1032)/F(1038)$ of 1.8. This result does not deviate much from the observed value of 1.7, as shown in Section 2.2. In Table 4, we summarize the intrinsic far-UV O VI parameters including, center wavelength, Raman scattering efficiency $\eta$, calculated number flux density $N_{\text{exp}}$, expected line flux $F_{\text{exp}}$, and the observed flux $F_{\text{obs}}$ in FUSE data.

### Table 4

| Line     | $\lambda$ (Å) | $\eta$ | $N_{\text{exp}}$ (s$^{-1}$) | $F_{\text{exp}}$ (erg cm$^{-2}$ s$^{-1}$) | $F_{\text{obs}}$ (erg cm$^{-2}$ s$^{-1}$) |
|----------|----------------|--------|-----------------------------|--------------------------------------|--------------------------------------|
| O VI 1032 | 1031.928       | 0.105  | $5.3 \times 10^{46}$        | $1.3 \times 10^{-9}$                  | $2.01 \times 10^{-10}$              |
| O VI 1038 | 1037.618       | 0.043  | $3.1 \times 10^{46}$        | $7.3 \times 10^{-10}$                  | $1.18 \times 10^{-10}$              |

4. O VI $\lambda$ 3811 and 3834 Doublet

The O VI $\lambda$ 3811 and 3834 lines arise from transitions between the level $1s^2 3p$ ($^3P_{1/2,3/2}$) and $1s^2 3s$ ($^3S_{1/2}$), respectively. We present a partial Grotrian diagram for O VI in Figure 7. O VI $\lambda$ 3811 appears in the optical line list of RR Tel by McKenna et al. (1997), who obtained a high-resolution spectrum in a wavelength range from 3430 to 9320 Å with a
and isoelectronic configurations with OVI. With a single Gaussian function, the N V doublet lines are located at 4602.85 Å and 4619.14 Å with FWHM = 48 km s\(^{-1}\) and 50 km s\(^{-1}\), respectively. The C IV doublets are found at 5800.22 Å and 5810.90 Å with FWHM = 43 km s\(^{-1}\) and 42 km s\(^{-1}\), respectively. Our fitting parameters with a single Gaussian function for the N V and C IV doublets are summarized in Table 5.

Our MIKE data shows that the 3811 emission feature has a single-peak profile with FWHM ~ 62 km s\(^{-1}\). To decompose it into O VI 3811 and O III 3810, the profile width of O III 3810 is derived from the adjacent O III emission line at 3791 Å, whose profile width is measured to be ~29 km s\(^{-1}\). Within the expected FWHM of 44 km s\(^{-1}\) for O VI 3811 and 29 km s\(^{-1}\) for O III 3810, we find that O VI 3811 is centered at 3810.74 Å with a line flux \(F(3811) = 1.5 \times 10^{-13} \text{erg cm}^{-2} \text{s}^{-1}\). The fitting result is shown in the left panel of Figure 8.

As shown in the right panel of Figure 8, the blended emission feature at 3834 Å has a complicated profile consisting of strong Balmer H9 λ 3835, two peaks and a blue shoulder, implying that the 3834 blend comprises at least four emission lines. For decomposition, we first analyze Balmer H9 3835 and He II 3833 lines by taking H8 3888 and He II 3887, and H7 3969 and He II 3967 as reference lines. The Balmer line profiles are well fitted using three emission components: a central main part, broad wings, and a red bump. The Balmer line fluxes are measured to be \(F(H7) = 2.5 \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1}\), \(F(H8) = 1.9 \times 10^{-12} \text{erg cm}^{-2} \text{s}^{-1}\), and \(F(H9) = 9.3 \times 10^{-13} \text{erg cm}^{-2} \text{s}^{-1}\). The flux ratio \(F(H7):F(H8):F(H9) = 1:0.78:0.37\) deviates from the case B recombination, which yields a declining trend 1: 0.66: 0.46.

He II 3887 and 3967 lines are fitted with a single Gaussian function with FWHM = 0.54 Å. Considering the flux ratio of Balmer lines and He II emissions, the blue shoulder located at around 3833 Å is plausibly identified with He II emission so that we use the term “He II 3833.” The multi-Gaussian fitting results for the Balmer and He II emission lines are presented in Figure 9 and Table 6.

We find one narrow peak with a small flux at 3833.29 Å. Using a single Gaussian, the FWHM is measured to be 20 km s\(^{-1}\), which is smaller than the O VI 3811 line (44 km s\(^{-1}\)). In this regard, we suggest that the narrow peak at 3833.29 Å is mainly contributed by the He I 3833 line.

Taking these three emission lines into account, we finally isolate O VI 3834 with a Gaussian function having the same FWHM (44 km s\(^{-1}\)) as that of O VI 3811. We locate the line center at 3833.67 Å and measure a flux of \(F(3834) = 8.9 \times 10^{-14} \text{erg cm}^{-2} \text{s}^{-1}\), resulting in \(F(3811)/F(3834) \sim 1.7\).
Figure 8. O VI λ3811 (left) and 3834 (right) doublet in MIKE spectrum. The observed data is shown by a thick solid line, and narrow lines represent fitting profiles. Isolated O VI profiles are shown by the gray shades.

Figure 9. Multi-Gaussian fitting of H7 3969 and He II 3967 (left) and H8 3888 and He II 3887 (right). The MIKE data is shown by thick solid line, and narrow lines represent fitting profiles.

Table 6

| Line   | Wavelength (Å) | FWHM (Å) | Peak (erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$) | Flux (erg cm$^{-2}$ s$^{-1}$) |

5. Discussion

The results obtained from our simulations are based on simple kinematics with a Keplerian disk with an asymmetric matter distribution. Heo et al. (2016) proposed that the density asymmetry of the accretion disk is responsible for the profile disparity in the Raman OVI features. The density distribution yielding the best-fit profiles is depicted in Figure 5, where we note that the highest density on the entering side is 3.5 times that of the most sparse region on the opposite side. In reality, the high contrast of the density profile can be made by the elliptical shape of the accretion disk or clumpy, irregular structures in the flow, which should be general features because of the shock front, accretion wake, or the unstable behavior in the wind accretion process. A number of numerical works of wind accretion in symbiotic stars produced a strong spiral shock and eccentric stream flow, supporting the local density enhancement (e.g., de Val-Borro et al. 2009, 2017). However, the 3D spatial information, including its elongation, scale height, and radial motion, etc., is mixed into the Raman OVI profile. To disentangle the properties and geometry of the accretion flow, further modeling combining 3D high-resolution SPH simulations for wind accretion is needed. In Figure 6, our best-fit Monte Carlo profile is insufficient to reproduce the red wing part of the Raman 6825 feature at $\Delta V \sim 70$ km s$^{-1}$ only with our accretion disk model. We point out that the red wing part can be explained with an additional component moving away from the binary orbital plane (e.g., Heo et al. 2016; Lee et al. 2019).

We also note that the blue peak of the Raman 7082 is far below the theoretical range. Taking into account the ratio of the Raman scattering cross-section for the OVI 1032 and 1038 photons $\sigma_{\text{Ram}}(1032)/\sigma_{\text{Ram}}(1038) = 3.04$ and their oscillation strength $\tau(1032)/\tau(1038) = 2$, the acceptable range of the $F(6825)/F(7082)$ should be $<6.08$. However, the MIKE data show that the flux ratio of the blue peaks $f_{\text{blue}}(6825)/f_{\text{blue}}(7082)$ is 9.7 in 2017. One possible explanation for the relative suppression of the Raman feature was suggested by Schmid et al. (1999), who proposed the diminution is due to the presence of molecular TiO transitions in the atmosphere and wind of the Mira component. As discussed in Section 2.1, however, the Mira of RR Tel is not visible in the optical wavelength. Hence its absorption lines can not be the reason to explain the suppression of the blue portion of the Raman 7082. Further investigation is needed to interpret the discrepancy between the theory and the observation.

In comparison with the FEROS spectrum taken in 2003, we note that the profiles of Raman OVI features have changed, their red peaks in the MIKE data being stronger. The variation of the Raman OVI profiles implies that the density distribution of the accretion disk has been more asymmetric in the last two decades. The increasing asymmetry of the matter distribution could be related to the dust obscuration episode that occurred between 1996 and 2000, which is associated with the enhancement of the mass-loss rate (Kotnik-Karauza et al. 2006; Jurkic & Kotnik-Karauza 2012).

We also found the OVI doublet at 3811 and 3834 Å, which are blended with other emission lines. Our profile decomposition leads us to investigate whether the OVI $\lambda\lambda$ 3811, 3834 doublet has a single Gaussian profile with a width of $\sim\text{44 km s}^{-1}$, corresponding to a physical size of $\sim0.5$ au. It is worth bearing in mind that the emission region of the OVI $\lambda\lambda$ 1032 and 1038 doublet has a representative scale of $<0.8$ au. This result is consistent with the idea that the OVI recombination lines are produced in the inner part closer to the WD than the OVI resonance lines proposed by Young (2012). Photoionization modeling is used to obtain the ionization structure of oxygen in the nebula. We conduct a simple exercise for a spherical geometry with a uniform density assuming physical parameters of hot WD, $L_W \sim 5000 L_\odot$ and $T_{\text{eff}} \sim 154,000$ K, adopted in our work. The exercise gives a hydrogen volume density $n(H) \sim 10^{4.6}$ cm$^{-3}$. Our estimation appears to be consistent with 3D hydrodynamical simulations of focused wind accretion in symbiotic stars by de Val-Borro et al. (2017, see their Figure 8). Their model with $a = 8$ au, $M \sim 10^{-6} M_\odot$ yr$^{-1}$, and $v_{\text{wind}} \sim 20$ km s$^{-1}$ produced the accretion stream around WD exceeding the local density $>10^{-6}$ g cm$^{-3}$. If we adopt the solar abundance, this value is translated into the hydrogen volume density of $n(H) > 10^9$ cm$^{-3}$. It should be noted that a direct comparison between our work and theirs is not feasible considering the different parameter sets adopted in this work.

The identification of the OVI $\lambda\lambda$ 3811 and 3834 doublet strongly supports the presence of the EUV doublet at 150.09 Å and 150.13 Å, originating from 3p $\rightarrow$ 2s transitions, as shown in Figure 7. Because of a small separation of $\Delta V \sim 80$ km s$^{-1}$ between two wavelengths, we expect a blended emission at 150.1 Å with a spectrograph having a spectral resolution $R < 10,000$. O VII is one of the highest observed stages of ionization in the RR Tel spectrum, and thus can provide a reliable diagnostic of high-temperature plasma. With future EUV observations, our analysis for the OVI and O VII groups could reveal important information on the ionization state and nebular physics in RR Tel.

6. Summary

RR Tel is a symbiotic nova, consisting of a Mira variable and a hot WD. It is known as one of the objects having broad emission features at 6825 and 7082 Å, which originate from Raman scattering of OVI 1032 and 1038 by neutral hydrogen atoms. In this work, we present optical high-resolution spectra of RR Tel obtained with MIKE and FEROS and the far-UV FUSE spectrum. We have performed Monte Carlo simulations for the profiles of the Raman OVI features, assuming a Keplerian disk. It allows us to map the OVI disk and estimates the representative scale of <0.8 au. The best-fit profiles are obtained with a mass-loss rate of the Mira $M \sim 2 \times 10^{-6} M_\odot$ yr$^{-1}$ and a wind terminal velocity $v_\infty \sim 20$ km s$^{-1}$. Comparison with FEROS data provides evidence of a change in the density asymmetry of the OVI disk, which can be associated with the mass-transfer history of RR Tel in the last two decades. We also identify OVI $\lambda\lambda$ 3811 and 3834 doublet from detailed profile decomposition, from which the physical scale of the O VII region is estimated to be $\sim0.5$ au. It is emphasized again that Raman profiles provide essential information regarding the matter distribution and kinematics of the H I and O VI components leading to the advancement of our knowledge on the stellar wind accretion in symbiotic stars. Combining 3D hydrodynamical modeling might improve our overall understanding of the WRLOF mode and the accretion phenomena in D-type symbiotic systems.

We would like to thank the anonymous referee for constructive comments that greatly improved this paper. We are also grateful to Young-Min Lee for valuable discussions.
