ABSTRACT

Context. The ratio of kinematic viscosity to thermal diffusivity, the Prandtl number, is much smaller than unity in stellar convection zones.

Aims. The main goal is to study the statistics of convective flows and energy transport as functions of the Prandtl number.

Methods. Three-dimensional numerical simulations of compressible non-rotating hydrodynamic convection in Cartesian geometry are used. The convection zone (CZ) is embedded between two stably stratified layers. The dominant contribution to the diffusion of entropy fluctuations comes in most cases from a subgrid scale (SGS) diffusivity whereas the mean radiative energy flux is mediated by a diffusive flux employing Kramers opacity law. Statistics and transport properties of up- and downflows are studied separately.

Results. The volume-averaged rms velocity increases with decreasing Prandtl number. At the same time the filling factor of downflows decreases and leads to, on average, stronger downflows at lower Prandtl numbers. This results in a strong dependence of convective overshooting on the Prandtl number. Velocity power spectra do not show marked changes as a function of Prandtl number except near the base of the convective layer where the dominance of vertical flows is more pronounced. At the highest Reynolds numbers the velocity power spectra are more compatible with the Bolgiano-Obukhov $k^{-11/5}$ than the Kolmogorov-Obukhov $k^{-5/3}$ scaling. The horizontally averaged convected energy flux ($\overrightarrow{F}_{\text{conv}}$), which is the sum of the enthalpy ($\overrightarrow{F}_{\text{enth}}$) and kinetic energy fluxes ($\overrightarrow{F}_{\text{kin}}$), is independent of the Prandtl number within the CZ. However, the absolute values of $\overrightarrow{F}_{\text{enth}}$ and $\overrightarrow{F}_{\text{kin}}$ increase monotonically with decreasing Prandtl number. Furthermore, $\overrightarrow{F}_{\text{enth}}$ and $\overrightarrow{F}_{\text{kin}}$ have opposite signs for downflows and their sum $\overrightarrow{F}_{\text{conv}}$ diminishes with Prandtl number. Thus the upflows (downflows) are the dominant contribution to the convected flux at low (high) Prandtl number. These results are similar to those from Rayleigh-Bénard convection in the low Prandtl number regime where convection is vigorously turbulent but inefficient at transporting energy.

Conclusions. The current results indicate a strong dependence of convective overshooting and energy flux on the Prandtl number. Numerical simulations of astrophysical convection often use Prandtl number of unity because it is numerically convenient. The current results suggest that this can lead to misleading results and that the astrophysically relevant low Prandtl number regime is qualitatively different from the parameters regimes explored in typical contemporary simulations.

Key words. turbulence – convection

1. Introduction

The flows in solar and stellar CZs are characterised by very high Reynolds and Péclet numbers $Re = u\ell/\nu$ and $Pe = u\ell/\chi$, respectively, where $u$ and $\ell$ are typical velocity and length scales, and $\nu$ and $\chi$ are the kinematic viscosity and thermal diffusivity (e.g. Ossendrijver 2003; Käpylä 2011; Schumacher & Sreenivasan 2020). This implies very vigorous turbulence which means that resolving all scales down to the Kolmogorov scale is infeasible (e.g. Chan & Sofia 1986). Moreover, the ratio $Pe/Re$, which is the Prandtl number $Pr = \nu/\chi$, is typically much smaller than unity in stellar CZs (e.g. Augustson et al. 2019).

For example, values of the order of $Pr \lesssim 10^{-6}$ are typical in the solar CZ. Most numerical simulations, however, are made with Prandtl number of the order of unity because greatly differing viscosity and thermal diffusivity would lead to a wide gap in the smallest physically relevant scales of velocity and temperature. Hence, reaching high $Re$ and $Pe$ simultaneously in simulations with low $Pr$ is prohibitively expensive (e.g. Kupka & Muthsam 2017).

Recently it has become clear that current simulations do not capture some basic features of solar convection accurately. Comparisons of helioseismic and numerical studies suggest that the simulations produce significantly higher velocity amplitudes at large horizontal scales (e.g. Hansaoge et al. 2012, 2016). While discrepancies exist also between helioseismic methods (see, e.g. Greer et al. 2015), there is another, more direct piece of evidence from simulations: global and semi-global simulations with solar luminosity and rotation rate preferentially lead to antisolar differential rotation with a slower equator and faster poles (e.g. Fan & Fang 2014; Käpylä et al. 2014; Karak et al. 2018).

This is indicative of a too weak rotational influence on the flow leading to a too high Rossby number. Simulations also suggest that convective velocities do not need to be off by more than 20–30 per cent for the rotation profile to flip (Käpylä et al. 2014). The discrepancy between simulations and observations has been dubbed the convective conundrum (O’Mara et al. 2016).

There are several possibilities why current simulations may overestimate convective velocity amplitudes. For example, the Rayleigh numbers in the simulations can be too low (e.g. Featherstone & Hindman 2016) or that convection in the Sun...
is driven only in thin near-surface layer, whilst the rest of the CZ is mixed by cool entropy rain emanating from the near-surface regions (Spruit 1997; Brandenburg 2016). In such scenarios the bulk of the CZ would be weakly subadiabatic while the convective flux would still be directed outward due to a non-local non-gradient contribution to the convective energy flux (Deardorff 1961, 1966). Such layers have been named Deardorff zones (Brandenburg 2016), and have been detected in many simulations (e.g. Chan & Giga 1992; Roxburgh & Simmons 1993; Tremblay et al. 2015; Hotta 2017; Käpylä et al. 2017). However, the effect of Deardorff layers on velocity amplitudes in rotating convection in spherical coordinates appears to be weak (Käpylä et al. 2019). Furthermore, while there is evidence of the importance of surface driving (e.g. Cossette & Rast 2016), it appears that this effect is also rather weak (Hotta et al. 2019).

Another possible cause of the discrepancy are the unrealistic Prandtl numbers typically used in simulations. It is numerically convenient to use \( Pr = 1 \), although several recent studies have explored the possibility that stellar convection might operate in a high effective turbulent Prandtl regime with \( Pr \) \( \gtrsim 1 \) (e.g. O’Mara et al. 2016; Bekki et al. 2017; Karak et al. 2018). A conclusion from these studies is that while the average velocity amplitude decreases as the Prandtl number increases, turbulent angular momentum transport is predominantly downward and leads to exacerbation of the anti-solar differential rotation issue at solar rotation rate and luminosity (Karak et al. 2018). Apart from the theoretical problem of explaining how the Sun switches from \( Pr \ll 1 \) suggested by microphysics to \( Pr \gg 1 \), the numerical studies appear to disfavor the possibility of an effective Prandtl number greater than unity in the Sun.

The small Prandtl number limit, which is indicated by estimates of molecular diffusivities in stellar CZs (e.g. Augustson et al. 2019; Schumacher & Sreenivasan 2020), has also been considered in various studies. An early work by Spiegel (1962) explored the limit of zero Prandtl number in Boussinesq convection. He showed that the temperature fluctuations are enslaved to vertical motions which leads to highly nonlinear driving of convection. Subsequent numerical studies in the low-\( Pr \) regime have shown that convection becomes highly inertial with a tendency for coherent large-scale flow structures to intensify (e.g. Breuer et al. 2004) along with vigorous turbulence. Studies of compressible convection have also explored the Prandtl number dependence, although its significance has gone largely unrecognized. For example, the results of Cattaneo et al. (1991) show that the net energy flux due to downflows is reduced as a function of \( Pr \), whereas the downward kinetic energy flux and upward enthalpy flux both increase as \( Pr \) decreases. These authors, however, did not connect this to the changing Prandtl number but rather as a consequence of an increase in the Reynolds number or the degree of turbulence. Results similar to those of Cattaneo et al. (1991) were reported also in Singh & Chan (1993). On the other hand, Brandenburg et al. (2005) found that the correlation coefficients of velocity and temperature fluctuations with the enthalpy flux remained \( Pr \)-dependent at least to Reynolds numbers of the order of \( 10^7 \). Finally, Orvedahl et al. (2018) studied non-rotating anelastic convection in spherical coordinates and found that the overall velocity amplitude increases as the Prandtl number decreases while the spectral distribution of velocity is insensitive to \( Pr \).

Here the Prandtl number dependence of convective flow statistics, overshooting, and energy fluxes are studied systematically with a hydrodynamic convection setup in Cartesian setup. A motivation of the current study is a prior work (Käpylä 2019b) where it was found that convective overshooting is sensitive to the Prandtl number and that earlier numerical results predicting weak overshooting for solar parameters were obtained from simulations where \( Pr \gtrsim 1 \) or \( Pr \gg 1 \). This implies a change in the magnitudes, dominant scales, or other transport properties, such as correlations with thermodynamic quantities of convective flows, all of which will be investigated in the present study. Overshooting is also closely related to the convective energy transport which is another focus of the current study. In particular, we will study the overall transport properties as a function of \( Pr \) and the respective roles of up- and downflows.

2. The model

The set-up used in the current study is the same as that in Käpylä (2019b). We solve the equations for compressible hydrodynamics

\[
\frac{D\ln\rho}{Dt} = -\nabla \cdot \mathbf{u}, \quad (1)
\]

\[
\frac{D\mathbf{u}}{Dt} = g - \frac{1}{\rho} (\nabla p - \nabla \cdot 2\nu \rho \mathbf{S}), \quad (2)
\]

\[
\frac{T \mathbf{D} \mathbf{S}}{Dt} = -\frac{1}{\rho} \nabla \cdot \left( \mathbf{F}_\text{rad} + \mathbf{F}_\text{SGS} + \Gamma_{\text{cool}} \right) + 2\nu \mathbf{S}^2, \quad (3)
\]

where \( D/Dt = \partial/\partial t + \mathbf{u} \cdot \nabla \) is the advective derivative, \( \rho \) is the density, \( \mathbf{u} \) is the velocity, \( g = -\sigma \mathbf{e}_z \) with \( \sigma > 1 \) is the acceleration due to gravity, \( p \) is the pressure, \( T \) is the temperature, \( s \) is the specific entropy, and \( \nu \) is the kinematic viscosity. Furthermore, \( \mathbf{F}_\text{rad} \) and \( \mathbf{F}_\text{SGS} \) are the radiative and turbulent SGS fluxes, respectively, and \( \Gamma_{\text{cool}} \) describes cooling near the surface. \( \mathbf{S} \) is the traceless rate-of-strain tensor with

\[
S_{ij} = \frac{1}{2} (u_{i,j} + u_{j,i}) - \frac{1}{3} \delta_{ij} \nabla \cdot \mathbf{u}. \quad (4)
\]

Radiation is modeled via the diffusion approximation, corresponding to an optically thick, fully ionized gas. The ideal gas equation of state \( p = (\gamma p - c_V r)T^2 = R \rho T \) is assumed, where \( R \) is the gas constant, and \( c_p \) and \( c_v \) are the specific heats at constant pressure and volume, respectively. The radiative flux is given by

\[
\mathbf{F}_\text{rad} = -K \nabla T, \quad (5)
\]

where \( K(\rho, T) \) is the radiative heat conductivity,

\[
K = \frac{16 \sigma_S T^3}{3 e \rho}, \quad (6)
\]

with \( \sigma_S \) being the Stefan-Boltzmann constant where \( \kappa \) is the opacity. The latter is assumed to obey a power law

\[
\kappa = \kappa_0 (\rho / \rho_0)^a(T/T_0)^b, \quad (7)
\]

where \( \rho_0 \) and \( T_0 \) are reference values of density and temperature. In combination, Eqs. (6) and (7) give

\[
K(\rho, T) = K_0 (\rho / \rho_0)^{-a(b+1)}(T/T_0)^{3-b}. \quad (8)
\]

With the choices \( a = 1 \) and \( b = -7/2 \) this corresponds to the Kramers opacity law (Weiss et al. 2004), which was first used in convection simulations by Brandenburg et al. (2000).

The fixed flux at the bottom of the domain \( F_{\text{bot}} \) fixes the initial profile of radiative diffusivity, \( \chi = K / (c_p \rho) \), which varies strongly as a function of height. Thus additional GBS diffusivity is added in the entropy equation to keep the simulations numerically feasible. Here the SGS flux is formulated as

\[
\mathbf{F}_\text{SGS} = -\rho T x_{\text{SGS}} \nabla s, \quad (9)
\]
where \( s' = s - \bar{s} \) is the fluctuation of the specific entropy from
the horizontally averaged mean which is denoted by an overbar.
The mean \( \bar{s} = \overline{s(z, t)} \) is computed at each timestep. The coefficient \( \chi_{\text{SGS}} \) is constant throughout the simulation domain\(^1\). The net horizontally averaged SGS flux is negligibly small, such that \( F_{\text{SGS}} \approx 0 \).

The cooling near the surface is given by
\[
\Gamma_{\text{cool}} = -\Gamma_0 b(z)[T'_{\text{cool}} - T(x, t)],
\]
where \( \Gamma_0 \) is a cooling luminosity, \( T = e/c_v \) is the temperature, \( e \) is the internal energy, and \( T_{\text{cool}} = T_{\text{top}} \) is the fixed reference temperature at the top boundary.

### 2.1. Geometry, initial and boundary conditions

The computational domain is a rectangular box where \( z_{\text{bot}} \leq z \leq z_{\text{top}} \) is the vertical coordinate. With \( z_{\text{bot}}/d = -0.45 \) and \( z_{\text{top}}/d = 1.05 \), where \( d \) is the depth of the initially isentropic layer (see below), the vertical extent is \( L_z = z_{\text{top}} - z_{\text{bot}} = 1.5d \). The horizontal size of the domain is \( L_H = 4d \) and the horizontal coordinates \( x \) and \( y \) run from \(-2d \) to \( 2d \).

The initial stratification consists of three layers such that the
lower two layers are polytropic with polytropic indices \( n_1 = 3.25 \) \( (z_{\text{bot}}/d \leq z \leq 0) \) and \( n_2 = 1.5 \) \( (0 \leq z/d \leq 1) \). The uppermost layer above \( z/d = 1 \) is initially isothermal with \( T = T_{\text{top}} \). The latter mimics a photosphere where radiative cooling is efficient. The initial stratification is set by the normalized pressure scale height at the top boundary
\[
\xi_0 = \frac{RT_{\text{top}}}{gd}. \tag{11}
\]

All of the current runs have \( \xi_0 = 0.054 \). The choices of \( n_1 \) and \( n_2 \) reflect the expected thermal stratifications in the radiative (see Barekat & Brandenburg (2014) and Appendix A of Brandenburg (2016)) and convective layers, respectively. Prior experience confirms these choices to be valid (see, e.g. Käpylä et al. 2019), although the extent of the CZ is an outcome of the simulation rather than fixed by the input parameters (Käpylä et al. 2017; Käpylä 2019b). Convection ensues because the system in initially in thermal inequilibrium.

The horizontal boundaries are periodic and on the vertical boundaries impenetrable and stress-free boundary conditions according to
\[
\frac{\partial u_x}{\partial z} = \frac{\partial u_y}{\partial z} = u_z = 0, \tag{12}
\]
are imposed. The temperature gradient at the bottom boundary is set according to
\[
\frac{\partial T}{\partial z} = -\frac{F_{\text{bot}}}{K_{\text{bot}}}, \tag{13}
\]
where \( F_{\text{bot}} \) is the fixed input flux and \( K_{\text{bot}}(x, y, z_{\text{bot}}, t) \) is the value of the heat conductivity at the bottom of the domain. On the upper boundary, constant temperature \( T = T_{\text{top}} \) coinciding with the initial value is assumed.

### 2.2. Units, control parameters, and simulation strategy

The units of length, time, density, and entropy are given by
\[
[x] = d, \quad [t] = \sqrt{d/g}, \quad [\rho] = \rho_0, \quad [s] = c_p, \tag{14}
\]
where \( \rho_0 \) is the initial value of density at \( z = z_{\text{top}} \). The models are fully defined by choosing the values of the kinematic viscosity \( \nu \), gravitational acceleration \( g \), the values of \( a, b, K_0, \rho_0, T_0, \) \( \Gamma_0 \) and the SGS and effective Prandtl numbers
\[
P_{\text{SGS}} = \frac{\nu}{\chi_{\text{SGS}}}, \quad P_{\text{eff}}(z) = \frac{\nu}{\chi_{\text{SGS}} + \chi(z)}, \tag{15}
\]
along with the cooling profile \( h(z) \). The values of \( K_0, \rho_0, T_0 \) are subsumed into a new variable \( K_0 = K_0/\rho_0^{n_1} \cdot T_0^{3/2} \) which is fixed by assuming \( F_{\text{rad}}(z_{\text{bot}}) = F_{\text{bot}} \) in the initial state. The profile \( h(z) = 1 \) for \( z/d \geq 1 \) and \( h(z) = 0 \) for \( z/d < 1 \), connecting smoothly over a layer of width \( 0.025d \). The normalized flux is given by
\[
F_n = F_{\text{bot}}/\rho_0^{n_1}u_{\text{r},\text{bot}}^3, \tag{16}
\]
where \( \rho_0 \) and \( c_s, \text{bot} \) are the density and the sound speed, respectively, at \( z_{\text{bot}} \) in the initial non-convecting state. The current runs have \( F_n \approx 4.6 \cdot 10^{-6} \) corresponding to runs K3 and K3h in Käpylä (2019b).

The advective terms in Eqs. (1) to (3) are formulated in terms of a fifth-order upwinding derivative with a hyperdiffusive sixth-order correction with a flow-dependent diffusion coefficient, see Appendix B of Dobler et al. (2006).

### 2.3. Diagnostics quantities

The following quantities are outcomes of the simulations that can only be determined a posteriori. These include the global Reynolds number and the SGS and effective Péclet numbers
\[
R_e = \frac{u_{\text{rms}}}{\nu/k_1}, \quad P_{\text{SGS}} = \frac{u_{\text{rms}}}{\chi_{\text{SGS}}k_1}, \quad P_{\text{e}}(z) = \frac{u_{\text{rms}}}{[\chi_{\text{SGS}} + \chi(z)]k_1}, \tag{17}
\]
where \( u_{\text{rms}} \) is the volume averaged rms-velocity and \( k_1 = 2\pi/d \) is an estimate of the largest eddies in the system.

To assess the level of supercriticality of convection the Rayleigh number is defined as:
\[
Ra(z) = \frac{gd}{\nu}[\chi_{\text{SGS}} + \chi(z)] - \frac{1}{c_p} \frac{ds}{dz}. \tag{18}
\]

The Rayleigh number varies as a function of height and is quoted near the surface at \( z/d = 0.85 \) for all models. Conventionally the Rayleigh number in the hydrostatic, non-convecting, state is one of the control parameters. In the current models with Kramers conductivity the convectively unstable layer in the hydrostatic case is very thin and confined to the near-surface layers (Brandenburg 2016). Thus the Rayleigh numbers are quoted from the thermally saturated statistically stationary states.

Contributions to the horizontally averaged vertical energy flux are:
\[
\begin{align*}
F_{\text{rad}} &= -K \frac{\partial T}{\partial z}, \tag{19} \\
F_{\text{enth}} &= c_p[\rho u_z]^2/\nu \tag{20} \\
F_{\text{kin}} &= \frac{1}{2} \rho u_z^2/\nu \tag{21} \\
F_{\text{visc}} &= -2\nu \rho u_z S_{1z} \tag{22} \\
F_{\text{cool}} &= \int_{z_{\text{bot}}}^{z_{\text{top}}} \Gamma_{\text{cool}} dz \tag{23}
\end{align*}
\]

Here the primes denote fluctuations and overbars horizontal averages. The total convected flux (Cattaneo et al. 1991) is the sum of the enthalpy and kinetic energy fluxes:
\[
F_{\text{conv}} = F_{\text{enth}} + F_{\text{kin}}. \tag{24}
\]
All of the runs discussed in the present study were branched off from run K3h of Käpylä (2019b), see Table 1 for a summary of the simulations. A thermally saturated snapshot of this run was used to produce new low resolution models, labeled the A set, at SGS Prandtl numbers ranging between 0.1 and 10. The runs in the intermediate (high) resolution set B (C) were remeshed from saturated snapshots of the corresponding runs in A (B) set. Only a subset of \( P_{\text{SGS}} \) values were done at the highest grid resolution in set C.

Table 1. Summary of the runs.

| Run | \( P_{\text{SGS}} \) | \( P_{\text{eff}} \) | \( P_{\text{Pr}} \) | Re | \( P_{\text{SGS}} \) | \( P_{\text{eff}} \) | \( P_{\text{Pr}} \) | \( R_a \) |
|-----|------------------|------------------|-----------------|----|------------------|-----------------|-----------------|----|
| A01 | 0.1 | 0.1 | 0.1 | 48 | 4.8 | 4.8 | 4.7 | 5.9 | 10^6 |
| B01 | 0.1 | 0.1 | 0.1 | 93 | 9.3 | 9.3 | 9.2 | 2.3 | 10^6 |
| C01 | 0.1 | 0.1 | 0.1 | 190 | 19 | 19 | 18 | 8.4 | 10^6 |
| C01b | 0.1 | 0.1 | 0.1 | 318 | 32 | 32 | 30 | 2.3 | 10^7 |
| C01c | 0.1 | 0.1 | 0.1 | 473 | 47 | 47 | 43 | 5.2 | 10^7 |
| A02 | 0.2 | 0.2 | 0.2 | 44 | 8.8 | 8.8 | 8.6 | 9.7 | 10^7 |
| B02 | 0.2 | 0.2 | 0.2 | 89 | 18 | 18 | 17 | 4.0 | 10^5 |
| C02 | 0.2 | 0.2 | 0.2 | 178 | 36 | 35 | 33 | 1.6 | 10^7 |
| A05 | 0.5 | 0.5 | 0.5 | 41 | 20 | 20 | 20 | 2.1 | 10^5 |
| B05 | 0.5 | 0.5 | 0.5 | 85 | 42 | 42 | 39 | 9.9 | 10^6 |
| A1 | 1.0 | 1.0 | 0.9 | 39 | 39 | 39 | 35 | 4.2 | 10^6 |
| B1 | 1.0 | 1.0 | 0.8 | 84 | 84 | 83 | 70 | 2.1 | 10^7 |
| C1 | 1.0 | 1.0 | 0.7 | 175 | 175 | 170 | 127 | 8.1 | 10^7 |
| A2 | 2.0 | 2.0 | 1.7 | 38 | 75 | 74 | 63 | 8.4 | 10^6 |
| B2 | 2.0 | 1.9 | 1.4 | 82 | 164 | 159 | 118 | 4.1 | 10^7 |
| A5 | 5.0 | 4.8 | 3.3 | 36 | 181 | 175 | 121 | 2.1 | 10^5 |
| B5 | 5.0 | 4.7 | 2.5 | 80 | 399 | 374 | 203 | 9.9 | 10^7 |
| A10d | 10 | 9.9 | 9.1 | 2.7 | 27 | 27 | 24 | 3.5 | 10^7 |
| A10c | 10 | 9.9 | 8.3 | 59 | 59 | 49 | 49 | 10 | 10^6 |
| A10b | 10 | 9.6 | 6.7 | 16 | 163 | 157 | 109 | 8.5 | 10^6 |
| A10 | 10 | 9.3 | 5.0 | 35 | 354 | 331 | 178 | 4.1 | 10^7 |
| B10 | 10 | 8.8 | 3.4 | 79 | 791 | 697 | 269 | 1.9 | 10^8 |
| C10 | 10 | 7.8 | 2.1 | 167 | 1667 | 1308 | 347 | 6.4 | 10^8 |

Notes. The superscripts top and bot refer to \( z/d = 0.85 \) and to the bottom of the CZ, \( z_{CZ} \), respectively. \( \Gamma_0 = 2.5c_B \left( g_B \right)^{1/2} \) in all of the runs. The grid resolutions are \( 288^3 \) (set A), \( 576^3 \) (B), and \( 1152^3 \) (C), respectively.

3.1. Flow characteristics

Figure 1 shows visualizations of the flows and entropy fluctuations in cases with \( P_{\text{SGS}} = 0.1, 1, \) and 10 (\( Re = 190, 175, \) and 167) corresponding to runs C01, C1, and C10. Visual inspection of the velocity patterns does not reveal notable differences at large scales such that the dominant granule sizes in the three cases are similar. Smaller scale structures in the velocity appear especially near the surface as the SGS Prandtl number increases; see the middle and bottom panels of Fig. 1. Nevertheless, the velocity patterns are remarkably similar in comparison to the entropy fluctuations which change dramatically as \( P_{\text{SGS}} \) increases from 0.1 to 10. In the \( P_{\text{SGS}} = 0.1 \) case the strong downflows coincide with smooth regions of negative (cool) entropy fluctuations, whereas the surrounding areas are almost featureless. In contrast, in the \( P_{\text{SGS}} = 10 \) case the smooth negative entropy regions have disintegrated into numerous smaller structures that are often detached from each other. The entropy fluctuations in the \( P_{\text{SGS}} = 1 \) run shows an intermediate behavior with traces of both large- and small-scale structures.

The averaged rms velocity as a function of \( u_{\text{rms}} \) from all runs is shown in Fig. 2. There is a tendency to increase with decreasing \( P_{\text{SGS}} \) which was first reported by Singh & Chan (1993) in compressible convection. Data for approximately constant \( P_e \) is suggestive of a power law with exponent around \(-0.13\), see the dotted lines in Fig. 2. A similar dependence can be seen in the suitably scaled data of non-rotating spherical shell simulations R0P[1,2,6] of Karak et al. (2018), see the crosses in Fig. 2. However, their run with the highest \( P_e \) (R0P20) appears to be an outlier. The results of Orvedahl et al. (2018) also indicate an increase of kinetic energy as the Prandtl number decreases. Furthermore, qualitatively similar results have been reported from Bousinesq convection (e.g. Breuer et al. 2004; Scheel & Schumacher 2016), although there the dependence of \( u_{\text{rms}} \) on \( P_e \) is much steeper. This is because in Rayleigh–Bénard convection the total flux transported by convection depends strongly on the Prandtl number.

A distinct characteristic of convection is that the vertical flows are the main transporter of the energy flux. A diagnostic of the structure of vertical flows is the filling factor \( f \) of up- or downflows. Here the filling factor is defined as the area of the downflows occupying at each depth such that the horizontally averaged vertical velocity us given by:

\[
\bar{u}_z(z) = f(z)\bar{u}^+ (z) \left[ 1 - f(z)\bar{u}^- (z)\right].
\]

where \( \bar{u}^- \) is the total vertical velocity whereas \( \bar{u}^+ \) and \( \bar{u}^- \), respectively, are the mean velocities in the down- and upflows. Figure 3(a) shows \( f \) for runs B01, B1, and B10 with \( P_{\text{SGS}} = 0.1, 1, \) and 10. These results indicate that the filling factor decreases with decreasing SGS Prandtl number. However, the change is relatively minor such that \( f \) differs by roughly 20 per cent in the bulk of the CZ between the extreme cases with \( P_{\text{SGS}} = 0.1 \) and 10. The filling factor plays an important role in analytic and semi-analytic two-stream models of convection (e.g. Rempel 2004; Brandenburg 2016). For example, in the updated mixing length model of Brandenburg (2016), a very small filling factor is needed in cases where the Schwarzschild unstable part of the CZ is particularly shallow. The current simulations suggest that the filling factor goes to that direction when \( \Gamma_0 \) decreases, but it appears that the smallest values of the order of \( 10^{-4} \) in some of the models of Rempel (2004) and Brandenburg (2016) are ruled out.

The filling factor increases as a function of Re and \( P_{\text{SGS}} \) for a given \( P_{\text{SGS}} \), see Fig. 3(b) for representative results for

Fig. 1. Left panels: Normalized vertical velocity $\tilde{u}_z = u_z(dg)^{-1/2}$ (colour contours) and streamlines of the flow from runs C01 ($Pr_{SGS} = 0.1$, top panel), C1 ($Pr_{SGS} = 1$, middle), and C10 ($Pr_{SGS} = 10$, bottom). The colours of the streamlines indicate the local vertical velocity. Right panels: normalized entropy fluctuations $\tilde{s}'(x) = [s(x) - \overline{s}(z)]/s'_{\text{rms}}(z)$ from the same runs.

$Pr_{SGS} = 0.1$ where $\chi_{SGS} \gg \chi$. It is plausible that a growing contribution from nearly isotropic small-scale eddies that become more prominent with increasing $Re$ is partly responsible for the increasing trend of $f$ as a function of the Reynolds number. However, preliminary studies using low-pass filtered data suggest that this effect is very subtle. Irrespective of the $Re$ dependence of $f$, the energetics of the underlying larger scale granulation appear to be almost unaffected by $Re$; see Section 3.3.

3.2. Overshooting below the convection zone

It is of interest to study the extent of convective overshooting below the CZ given the systematic dependence of the overall convective velocities on $Pr_{SGS}$. The same definition of overshooting as in Käpylä (2019b) is used. This is outlined by defining the bottom of the CZ ($z_{CZ}$) to be the depth where $F_{\text{conv}}$ changes from positive to negative. This depth is used to obtain a reference value of the horizontally averaged kinetic energy.
Käpylä: Prandtl number dependence of compressible convection

Fig. 2. Volume and time averaged rms velocity as a function of $\text{Pr}_{\text{eff}}(z_{\text{CZ}})$ for all of the current runs (circles). The colours (sizes) of the symbols indicate the Péclet number (relative error) as indicated in the colour bar (legend). The dotted lines show power laws proportional to $\text{Pr}_{\text{eff}}^{-0.13}$ for reference. The crosses show the scaled results from the non-rotating runs R0P[1,2,6,20] of Karak et al. (2018); see their Table 1.

flux $F_{\text{kin}}^{\text{ref}} = F_{\text{kin}}(z_{\text{CZ}},t)$. The instantaneous overshooting depth $z_{\text{OS}}$ is then taken to be the depth where $F_{\text{kin}}(z,t)$ drops below $10^{-2}F_{\text{kin}}^{\text{ref}}$. The mean thickness of the overshoot layer is defined as

$$d_{\text{os}} = \frac{1}{\Delta t} \int_{t_0}^{t_1} [z_{\text{CZ}}(t) - z_{\text{OS}}(t)] dt,$$

where $\Delta t = t_1 - t_0$, where $t_0$ and $t_1$ denote the beginning and end of the time averaging period.

Figure 4 shows $d_{\text{os}}$ from all runs as a function of $\text{Pr}_{\text{SGS}}$. The current results confirm the conjecture of Käpylä (2019b) that $d_{\text{os}}$ is sensitive to the Prandtl number. However, the results still depend on the Péclet number especially for low $\text{Pr}_{\text{SGS}}$ where it is challenging to reach high values of Pe. Nevertheless, comparing $d_{\text{os}}$ for approximately the same Pe, for example $\text{Pe} \approx 40$ (light blue symbols in Fig. 4), shows that the overshooting is increasing monotonically as $\text{Pr}_{\text{SGS}}$ decreases. The difference of $d_{\text{os}}$ between the cases $\text{Pr}_{\text{SGS}} = 1$ and $\text{Pr}_{\text{SGS}} = 0.1$ is about 30 per cent. However, the difference is decreasing as the Péclet number increases but it does not appear likely that the Pr dependence would disappear at even higher Péclet numbers.

Several numerical studies have shown that the deep parts of density stratified CZs are often weakly stably stratified (e.g. Chan & Gigas 1992; Tremblay et al. 2015; Bekki et al. 2017; Hotta 2017; Käpylä et al. 2017). Such layers have also been found from semi-global and global simulations of rotating solar-like CZs (e.g. Karak et al. 2018; Käpylä et al. 2019; Viviani & Käpylä 2021) as well as from fully convective spheres (Käpylä 2021). We call this layer the Deardorff zone after Brandenburg (2016). This layer is characterised by a positive vertical gradient of entropy, $ds/dz > 0$, along with a positive convective energy flux, $F_{\text{conv}} > 0$. The mean thickness of the Deardorff zone is defined similarly as $d_{\text{DZ}}$ via

$$d_{\text{DZ}} = \frac{1}{\Delta t} \int_{t_0}^{t_1} [z_{\text{DZ}}(t) - z_{\text{CZ}}(t)] dt,$$

where $z_{\text{DZ}}$ is the depth where the entropy gradient changes sign. The results for $d_{\text{DZ}}$ are shown in Fig. 5. At first glance, $d_{\text{DZ}}$ shows an opposite trend in comparison to $d_{\text{os}}$ such that it decreases with the Prandtl number but the dependence on Péclet and Reynolds numbers is again strong, particularly for low $\text{Pr}_{\text{SGS}}$. However, considering only the largest Pe for each $\text{Pr}_{\text{eff}}$, $d_{\text{DZ}}$ is roughly constant around $0.45H_p$ for $\text{Pr}_{\text{eff}} \lesssim 3$. 

Fig. 3. Filling factor of downflows for SGS Prandtl numbers 0.1 (solid line), 1 (dashed), and 10 (dash-dotted) as indicated by the legend from runs B01, B1, and B10 (a). Filling factor in runs with $\text{Pr}_{\text{SGS}} = 0.1$ with different $\text{Pe}_{\text{SGS}}$ (b). The vertical dotted lines indicate the depths from which representative data for the top, middle, and bottom of the CZ are considered.

Fig. 4. Thickness of the overshoot layer $d_{\text{os}}$ normalized by the pressure scale height $H_p(z_{\text{CZ}})$ for all runs as a function of $\text{Pr}_{\text{eff}}(z_{\text{CZ}})$. The colours (sizes) of the symbols indicate the Péclet number (relative error) as indicated in the colour bar (legend).
3.3. Flow statistics and spectral distribution

A standard diagnostics in flow statistics is the probability density function (PDF) which is defined by:

$$\int \mathcal{P}(u_i) du_i = 1.$$  \hspace{1cm} (28)

The moments of the PDF carry information about the statistical properties of the flow. Horizontally averaged instantaneous moments are given by:

$$\mathcal{M}^n(u_i, z) = \frac{1}{L_H} \int_{-L_H/2}^{L_H/2} \int_{-L_H/2}^{L_H/2} \left[ u_i(x) - \overline{u}_i(z) \right]^n dx dy.$$  \hspace{1cm} (29)

Here we study the skewness $S$ and the kurtosis $\mathcal{K}$ of the velocity field:

$$S = \frac{M^3}{\sigma_u^3}, \quad \mathcal{K} = \frac{M^4}{\sigma_u^4}, \quad \text{where} \quad \sigma_u = (M^2)^{1/2}.  \hspace{1cm} (30)$$

Representative PDFs of the velocity components near the surface, at the middle and near the base of the CZ from run C01 are shown in Fig. 6. The data is obtained by time-averaging over several snapshots. The horizontal flows have zero means and they have symmetric distributions around the mean. The vertical flows, on the other hand, show a bimodal distribution corresponding to the characteristic up- and downflow structure of convective granulation which is particularly clear near the surface. Similar results have been reported from a number of earlier numerical studies in different contexts and set-ups (e.g. Brandenburg et al. 1996; Miesch et al. 2008; Hotta et al. 2015).

Figure 7 shows $S$ and $\mathcal{K}$ as functions of depth from runs C01, C1, and C10. The skewness of the horizontal flows is essentially zero in all of the cases which is expected because no systematic horizontal anisotropy is present. $S$ is consistently negative and decreasing with depth for vertical flows within the CZ. This is indicative of a growing difference between the statistics of up- and downflows in the deeper parts. The kurtosis indicates a nearly Gaussian distribution with $\mathcal{K} \approx 3$ for both vertical and horizontal flows near the surface ($z/d \approx 0.9$). However, $\mathcal{K}$ increases as a function of depth such that $\mathcal{K} \approx 5$ for $u_x$ and $u_y$, and greater than ten for $u_z$ at the base of the CZ indicating strong non-Gaussianity. The skewness and kurtosis do not change significantly in the CZ as a function of $P_{\text{SGS}}$. The results for $S$ and $\mathcal{K}$ are in agreement with those of Hotta et al. (2015) and similar to the rotating spherical shell simulations of Miesch et al. (2008) notwithstanding the horizontal anisotropy in the latter. Finally, $\mathcal{K}$ obtains very high values in the overshoot regions especially for low $P_{\text{SGS}}$, see left panel of Fig. 7. This is most likely due to the highly intermittent turbulence due to the limited number of deeply penetrating plumes in these regions.

Next we study the velocity amplitudes as functions of spatial scale from power spectra of the velocity field,

$$E_K(k, z, t) = \frac{1}{2 \pi} \sum_k |\hat{u}(k, z, t)|^2,$$  \hspace{1cm} (31)

where $k = \sqrt{k_x^2 + k_y^2}$ is the horizontal wavenumber and the hat denotes a two-dimensional Fourier transform. The power spectra are computed from between ten to 40 snapshots depending on the run and then time-averaged. Furthermore, normalization is applied such that

$$\bar{E}_K(k, z, t) = \frac{1}{\Delta T} \int_{T_0}^{T_1} \int_{\Delta k_{\text{grid}}}^{\Delta k_{\text{grid}}} E_K(k, z, t) \Delta T \Delta k_{\text{grid}}.$$  \hspace{1cm} (32)

where $\Delta k_{\text{grid}} = \pi x_H/2$ is the Nyquist scale of the horizontal grid with $\pi x_H$ grid points. With this normalization the differences in the shape of the spectra are highlighted whereas the differences in the absolute magnitude are hidden. This is justified here because we are currently interested in the effects of the Prandtl number on the distribution of power as a function of spatial scale.

Representative results for $P_{\text{SGS}} = 0.1, 1,$ and 10 are shown in Fig. 8 from runs C01, C1, and C10. The differences in $E_K$ are small and most clearly visible at high wavenumbers near the surface and near the base of the CZ. The power at largest scales ($k/k_H < 3$) is similar in all cases and the clearest differences are seen at the base of the CZ although even these features are not particularly pronounced. It is possible that the horizontal extent of the domain is too small to capture the largest naturally excited scales because the peak of the power spectrum is always near the box scale. The spectra show a scaling that is consistently steeper than the Kolmogorov-Obukhov $k^{-5/3}$ spectrum. The Bolgiano-Obukhov scaling (Bolgiano 1959; Obukhov 1959) with $k^{11/5}$ is more compatible with the data especially at large $Re$; see also Fig. 11. However, the inertial range even in the current highest resolution simulations is very limited and the conclusions regarding scaling properties are quite uncertain. Furthermore, there is a puzzling spread of scaling exponents from convection simulations: early studies with modest inertial ranges suggested a $k^{-5/3}$ scaling (e.g. Cattaneo et al. 1991; Brandenburg et al. 1996; Porter & Woodward 2000) whereas more recent studies (e.g. Hotta et al. 2015; Featherstone & Hindman 2016) suggest clearly shallower scalings. On the other hand, power spectra of solar surface convection suggest significantly steeper (Yelles Chaouche et al. 2020, and references therein) scaling.

To study the anisotropy of the flow, the power spectra of vertical and horizontal velocities are defined as

$$\int_0^{k_{\text{max}}} E_V(k, z) dk = \frac{1}{2} \left[ u_x^2(z) + u_y^2(z) \right].$$  \hspace{1cm} (33)

$$\int_0^{k_{\text{max}}} E_H(k, z) dk = \frac{1}{2} \left[ u_x^2(z) + u_y^2(z) \right].$$  \hspace{1cm} (34)

The same averaging and normalization as above are applied here. Representative results from the same runs as in Fig. 8 are shown in Fig. 9. The horizontal and vertical velocity power spectra

![Fig. 5. Thickness of the Deardorff layer $d_{DCZ}$ normalized by the pressure scale height $H_p(S_{DCZ})$ for all runs as a function of $P_{\text{SGS}}$.](image-url)
at all depths indicate a dominance of horizontal flows at large scales ($k \lesssim 3$) whereas vertical flows are dominant for larger $k$. The scaling of $E_H$ is consistently steeper than the Kolmogorov-Obukhov $k^{-5/3}$ dependence.

The differences between runs are, however, again small with the exception of the bottom of the CZ ($z = 0.13d$) where a reduction of $E_H$ at large scales $k/k_H \lesssim 4$ for $Pr_{SGS} = 0.1$ is seen. The changes in the spectra are rather subtle and an alternative way to study the spectral distribution of velocity is to consider the spectral anisotropy parameter $A_V$ which is defined as
Fig. 9. Normalized power spectra of vertical ($E_V$, solid lines) and horizontal velocities $E_H$, dashed) from the same depths and runs as in Fig. 8. The inset shows low wavenumber contributions.

Fig. 10. Spectral vertical anisotropy parameter $A_V(k)$ according to Eq. (35) from near the surface ($z = 0.85d$, left panel), middle ($z = 0.49d$, middle), and near the bottom of the CZ ($z = 0.13d$, right) for the same runs as in Fig. 8.

(Käpylä 2019a):

$$A_V(k, z) \equiv \frac{E_H(k, z) - 2E_V(k, z)}{E_K(k, z)}.$$  (35)

Results for $A_V$ for the same runs as in Figs. 8 and 9 are shown in Fig. 10. Near the surface the large scales are dominated by horizontal flows such that $A_V(k) > 0$ for $k < 4$. The large-scale anisotropy for $k/k_H < 10$ is essentially identical for the three simulations shown in Fig. 10. The run with the highest Pr$_{SGS}$ starts to deviate from the other two for $k/k_H > 10$, and the two remaining runs deviate for $k/k_H \gtrsim 150$. Given that the energy transport is dominated by scales for which $k/k_H \lesssim 30$ (see below), it is likely that the differences of $A_V$ at large $k/k_H$ are not of great importance. The anisotropy at the middle of the CZ is remarkably similar for all three cases such that significant deviations occur only for $k/k_H \gtrsim 10$, see the middle panel of Fig. 10. The situation changes dramatically at the base of the CZ: while $A_V$ is essentially the same for all Prandtl numbers for $k/k_H > 8$, the results systematically deviate at larger scales. That is, the flow at largest scales ($k/k_H = 1$) continues to be horizontally dominated for all Prandtl numbers but $A_V$ is decreasing monotonically with Pr$_{SGS}$ such that for Pr$_{SGS} = 0.1$, $A_V$ change of sign from positive to negative already for $k/k_H > 1$. This is reflecting the stronger downflows and deeper overshooting in the low-Pr$_{SGS}$ regime.

Figure 11 shows normalized velocity power spectra compensated by $k^{11/5}$ from five runs with Pr$_{SGS} = 0.1$ where the Reynolds number varies between 48 and 473. This figure shows that the scaling of the velocity spectra for the highest Reynolds numbers at low Pr$_{SGS}$ is close to or even steeper than the Bolgiano-Obukhov $k^{-11/5}$ scaling. This is particularly clear at the middle and at the base of the CZ while no clear scaling can be discerned near the surface. Evidence for the Bolgiano-Obukhov scaling for the kinetic energy spectrum has previously been reported from simulations Rayleigh-Bénard convection (e.g. Calzavarini et al. 2002) as well as from corresponding shell models (Brandenburg 1992). However, the generality of the results for the spectra remain in question as stated earlier.

The current results indicate that increasing Re, and therefore increasing Ra, does not change the distribution of velocity power in wavenumber space significantly. This is in apparent contradiction with the results of Featherstone & Hindman (2016) who reported an increase of small-scale flow amplitudes at the expense of large-scale power as the Rayleigh number was increased. However, in their study the increase of the Rayleigh number was associated with a significant change in the fraction of the energy flux that is carried by convection because their SGS entropy diffusion contributes to the mean energy flux, see their Figure 6. It also appears that when the Rayleigh number is sufficiently large, the decrease of the large-scale power ceases also for Featherstone & Hindman (2016); see their Figure 3. In
Fig. 11. Power spectra of the velocity compensated by $k^{1/5}$ from near the surface ($z = 0.85d$, left panel), middle ($z = 0.49d$, middle), and near the bottom of the CZ ($z = 0.13d$, right) for $Pr_{SGS} = 0.1$ as a function of the SGS Péclet number as indicated by the legend. The spectra are normalized such that the contributions from $k/k_H = 1$ coincide.

Fig. 12. Power spectra of entropy fluctuations $\tilde{E}_S(k)$ compensated by $k^{1/6}$ from near the surface ($z = 0.85d$, left panel), middle ($z = 0.49d$, middle), and near the bottom of the CZ ($z = 13d$, right) for runs C01 (black lines), C1 (blue), and C10 (red). The spectra are normalized such that the contributions from $k/k_H = 1$ coincide.

In the present study the convective flux is not directly influenced by the SGS entropy diffusion and thus the current results differ qualitatively from those of Featherstone & Hindman (2016).

Figure 12 shows compensated power spectra of specific entropy fluctuations from runs C01, C1, and C10. The spectra are compensated by $k^{1/6}$ which appears to be compatible with the highest Pe cases. In $Pr_{SGS} = 0.1$ there is no clear inertial range due to the low Péclet number in run C01. In runs C1 and C10 where the Péclet number is larger the entropy fluctuations show roughly a $k^{-11/6}$ scaling at intermediate scales near the surface and at the middle of the CZ (top and middle panels of Fig. 12). Near the base of the CZ, only run C10 with the highest Pe shows signs of $k^{-11/6}$ spectra. The observed scaling is steeper than those from the Kolmogorov-Obukhov and Bolgiano-Obukhov models that predict $k^{-5/3}$ and $k^{-7/5}$, respectively. Based on the current results, it appears that the scaling of $E_S$ is becoming progressively shallower as Pe increases such that neither of the theoretical predictions can be ruled out at the moment. However, simulations at even higher resolutions are needed to confirm this.

3.4. Convective energy transport

Figure 13 shows the, enthalpy, kinetic energy, and total convected fluxes, Eqs. (20), (21), and (24), respectively, for the runs in the B set with $Re = 79 \ldots 93$ and $576^3$ grid. Remarkably, $F_{conv}$ is practically identical within the CZ in all of the runs irrespective of the SGS Prandtl number. This indicates that the radiative flux and hence the thermal stratification and radiative conductivity are very similar in all of the runs. The constituents of the convective flux, however, show a very different behavior: the enthalpy flux increases and the kinetic energy flux decreases monotonically with $Pr_{SGS}$. In particular, the kinetic energy flux more than doubles as $Pr_{SGS}$ decreases from 10 to 0.1. For the lowest $Pr_{SGS}$ the downward kinetic energy flux exceeds $F_{bot}$ near the middle of the CZ while $F_{enth}$ is almost twice $F_{bot}$. In contrast to the CZ, the convected flux in the overshoot layer shows much larger differences between different Prandtl numbers.

The contributions of up- and downflows to the enthalpy, kinetic energy and total convected flux $F_{conv}$ are shown in Fig. 14. The contributions of the upflows to $F_{enth}$ and $F_{kin}$ increase monotonically as $Pr_{SGS}$ decreases, leading to a net increase of the convected flux $F_{conv}^\uparrow$. The magnitudes of $F_{enth}^\downarrow$ and $F_{kin}^\downarrow$ also increase as the SGS Prandtl number decreases but the net $F_{conv}^\downarrow$ decreases because $F_{enth}^\downarrow$ and $F_{kin}^\downarrow$ have opposite signs. Remarkably, $F_{enth}$ and $F_{kin}$ are almost identical above $z/d \approx 0.9$ irrespective of $Pr_{SGS}$, suggesting that near-surface
Käpylä: Prandtl number dependence of compressible convection

Fig. 13. Normalized enthalpy (red), kinetic energy (blue), and convected (black) fluxes for the SGS Prandtl numbers ranging from 0.1 to 10 as indicated by the legend from the B set of runs with $Re = 79 \ldots 93$.

physics are not the cause of the differences discussed here. In total, the up- and downflows transport on average an equal fraction of $\tilde{F}_{\text{conv}}$ for SGS Prandtl number unity. The upflows are clearly dominant for the lowest SGS Prandtl numbers such that for $Pr_{\text{SGS}} = 0.1$ the upflows transport roughly two thirds of the convected flux within the CZ. An opposite, albeit weaker, trend is seen for $Pr_{\text{SGS}} > 1$. The results for $Pr_{\text{SGS}} \neq 1$ are thus qualitatively different from the case $Pr_{\text{SGS}} = 1$, and the difference increases towards large and small Prandtl numbers. The current results are also in accordance with those of Cattaneo et al. (1991) who found that in their more turbulent cases the contribution of the downflows to $F_{\text{conv}}$ was diminishing. The increase in the level of turbulence in their cases was associated with a decreasing Prandtl number $\sigma$. In their simulations the contribution of the downflows to the convected flux is practically negligible at $\sigma = 0.1$, see their Fig. 14d.

An important caveat of the current results is that changing $Pr_{\text{SGS}}$ implies also that the Péclet number is changing. Thus it is necessary to test whether the observed differences are really due to the Prandtl number and not because of a Péclet number dependence. Such a check is shown in Fig. 15 where the convected flux from the five simulations with $Pr_{\text{SGS}} = 0.1$ (A01, B01, C01, C01b, and C01c) are compared. The Reynolds and Péclet numbers differ by an order of magnitude in this set of runs. The differences are minor within the CZ whereas somewhat larger deviations are seen in the depth of the overshoot region. Nevertheless, the results are robust enough within the parameter range explored here such that the conclusions drawn regarding the energy fluxes remain valid. However, the current results should still be considered with some caution as the Péclet numbers studied thus far are still modest compared to realistic stellar conditions.

Although the statistics of velocity and entropy fluctuations do not show drastic changes as a function of $Pr_{\text{SGS}}$, yet the convective energy transport is strongly affected. In the following the same procedure as in Nelson et al. (2018) is used to study the dominant scales in the different contributions to the convective flux. First, a low-pass filter is applied to the quantities that enter the expressions of the fluxes such that wavenumbers $k < k_{\text{max}}$ are retained. For the enthalpy (kinetic energy) flux this applies to the fluctuating vertical momentum flux $(\rho u z)'$ and temperature fluctuation $T'$ (kinetic energy $E_{\text{kin}} = \frac{1}{2} \rho u^2$ and vertical velocity $u_z$). Then the normalized, horizontally averaged, enthalpy and kinetic energy fluxes up to $k_{\text{max}}$ are computed according to

$$\tilde{F}_{\text{enth}}(k_{\text{max}}, z) = \frac{1}{\Delta t} \int_{t_0}^{t_1} \left[ \frac{(\rho u z)'(z, k_{\text{max}}, t) T'(z, k_{\text{max}}, t)}{\tilde{F}_{\text{enth}}(z, t)} \right] dt, \quad (36)$$

$$\tilde{F}_{\text{kin}}(k_{\text{max}}, z) = \frac{1}{\Delta t} \int_{t_0}^{t_1} \left[ \frac{E_{\text{kin}}(z, k_{\text{max}}, t) u_z(z, k_{\text{max}}, t)}{\tilde{F}_{\text{kin}}(z, t)} \right] dt. \quad (37)$$

Fig. 14. Contributions from upflows (a) and downflows (b) on the horizontally averaged convected (black lines), enthalpy (red), and kinetic energy (blue) fluxes for the same runs as in Fig. 13.

Fig. 15. Comparison of total convected flux (black) and the contributions of the upflows (red) and downflows (blue) between runs A01, B01, C01, C01b, and C01c with $Pr_{\text{SGS}} = 0.1$. 

The current results thus suggest that convection becomes less efficient when the Prandtl number is decreased such that a larger vertical velocities are required to carry the same flux. This has some parallel in Rayleigh-Bénard convection where the Nusselt number decreases strongly for a given Rayleigh number when $Pr$ is decreased (Schumacher & Sreenivasan 2020, and references therein). This means that low Prandtl number convection is very turbulent but at the same time inefficient in transporting heat. The analogy to the Rayleigh-Bénard case is, however, not complete as in the current simulations the ratio of convective to radiative flux is almost unchanged when the SGS Prandtl number changes. Therefore the effects of the Prandtl number are not complete as in the current simulations the ratio of convective to radiative flux is almost unchanged when the SGS Prandtl number changes. The fact that the magnitudes of enthalpy and kinetic energy fluxes both increase as the SGS Prandtl number decreases while the convective energy transport.

The temperature fluctuations, shown in Fig. 17(b), show a somewhat more complex behavior: near the surface $T'_{\text{rms}}$ increases with $Pr_{\text{SGS}}$ whereas in deeper parts the trend is reversed. This can be understood such that near the surface the temperature fluctuations are mostly in small-scale structures such as granules and intergranular lanes which are subject to stronger diffusion for smaller $Pr_{\text{SGS}}$, resulting in smaller $T'_{\text{rms}}$ on average there. In the bulk of the CZ, $T'_{\text{rms}}$ is the largest for the smallest $Pr_{\text{SGS}}$ for both up- and downflows. This can partly explain the dominance of upflows in the energy transport for $Pr_{\text{SGS}} = 0.1$. For $Pr_{\text{SGS}} = 1$ and 10, $T'_{\text{rms}}$ is always larger in the latter, which is due to the lower thermal diffusivity. Finally, Fig. 17(c) shows the depth dependence of the rms density fluctuations. Here a monotonic trend is seen such that $\rho'_{\text{rms}}$ decreases with $Pr_{\text{SGS}}$. The correlation coefficient of vertical velocity and temperature fluctuations is given by

\[ C[u_z, T'] = \frac{u_z T'}{u_{z\text{rms}} T_{\text{rms}}} \approx \frac{\overline{F}_{\text{enth}}}{\overline{F}_{\text{kin}}}, \tag{38} \]

where $\overline{F}_{\text{enth}} = c_P (\rho u_z)'T' \approx c_P \rho u_z' T'$. The correlation coefficients $C[u_z, T']$ for the total flow, and up- and downflows for the same runs as in Fig. 17 are shown in Fig. 18. The overall correlation coefficient $C[u_z, T']$ decreases monotonically as $Pr_{\text{SGS}}$
3.6. Driving of convection

The dependence of the convective flows on the Prandtl number raises the question of their driving. A primary candidate is the entropy gradient at the surface which has indeed reported to be Prandtl number dependent (e.g. Brandenburg et al. 2005). A diagnostic of this is the maximum value of the superadiabatic temperature gradient

$$\Delta \nabla = \nabla - \nabla_{ad} = -\frac{H_p ds}{c_p dz},$$

where $\nabla = \partial \ln T / \partial \ln p$ and $\nabla_{ad} = 1 - 1/\gamma$ are the logarithmic and adiabatic temperature gradients, respectively. Figure 19 shows the maximum value of $\Delta \nabla$ near the surface for the total entropy as well as for the upflow and downflow regions separately for all of the current runs. The results for max($\Delta \nabla$) show a decreasing trend as a function of $P_{\text{eff}}$ and only a much weaker dependence on $P_{\text{eff}}$. The data perhaps suggests a $(\ln P_{\text{eff}})^{-1}$ dependence. A similar decreasing trend is seen in the upflow regions although the scatter in the data is stronger especially in the intermediate range of $P_{\text{eff}}$. On the other hand, the data for the downflows perhaps suggests a plateau for $P_{\text{eff}} \gtrsim 30$. However, these tentative dependences are rather uncertain due to the limited data available. Nevertheless, it appears that for approximately the same Péclet number the entropy gradient increases with the Prandtl number. This is opposite to the trend in the strength of downflows and thus the surface entropy gradient cannot be the dominant contribution in driving the downflows.

Next we turn to the force balance for vertical flows. The horizontally averaged force density is given by

$$F_z = \rho Du_z / D_t,$$

where $D/D_t = \partial / \partial t - u \partial / \partial z$ is the vertical advective time derivative. Representative results for the total force are shown in Fig. 20(a) for runs C01, C1, and C10. The runs with SGS Prandtl numbers 1 and 10 show a small difference near the surface in that the maximum total force is slightly larger for the lower Prandtl number. On the other hand, $F_z$ for $P_{\text{SGS}} = 0.1$ shows a markedly wider negative region in the upper part of the CZ between $0.65 \lesssim z/d \lesssim 0.9$. The force on the upflows is shown in Fig. 20(b). The differences between the two higher SGS Prandtl numbers are very small whereas the $P_{\text{SGS}} = 0.1$ case again shows a clear difference in the near-surface layers such that the region where upflows are decelerated is significantly wider.

Remarkably, $F_z$ is in almost perfect anticorrelation with the superadiabatic temperature gradient in the upflows ($\Delta \nabla$) such that upflows are decelerated (accelerated) in unstably (stably) stratified regions. This suggests that the upflows are not directly driven by the convective instability itself but rather by pressure forces induced by the deeply penetrating downflows (see also Körre et al. 2017; Käpylä et al. 2017). Finally, Fig. 20(c) shows the forces for the downflows. The downward force on the downflows is larger near the surface for $P_{\text{SGS}} = 0.1$ than in the cases with $P_{\text{SGS}} = 1$ and 10 which explains the stronger vertical velocities for low SGS Prandtl numbers. The force on the downflows is almost in anticorrelation with the overall superadiabatic temperature gradient.
Fig. 20. Horizontally averaged forces for the total flow (a), upflows (b) and downflows (c) for runs C01 ($Pr_{SGS} = 0.1$, solid lines), C1 ($Pr_{SGS} = 1$, dashed), and C10 ($Pr_{SGS} = 10$ dash-dotted). The blue and red lines show the corresponding superadiabatic temperature gradients with blue denoting negative and red positive values. The grey lines in panels (b) and (c) indicate $\Delta \nabla$ for reference.

abatic temperature gradient; compare the grey and black lines in Fig. 20(c).\(^3\) The correlation with $\Delta \nabla^4$ is clearly poorer.

Fig. 17(c) showed that the density fluctuations are weakly decreasing with $Pr_{SGS}$ such that the increased acceleration on the downflows cannot be explained by arguing that the matter in the downflows is cooler and heavier in the low $Pr_{SGS}$ cases in comparison to the higher $Pr_{SGS}$ cases. On the other hand, Fig. 18 shows that the correlation between vertical velocity and temperature fluctuations increases with decreasing $Pr_{SGS}$ which is the decisive factor in the enhanced acceleration of downflows. A similar enhancement of correlation is likely to carry over to other thermodynamic quantities as well. It is not clear what the exact mechanisms is but it seems plausible to assume that a process similar to the positive feedback loop between vertical flows and the buoyancy force in the zero Prandtl number limit in Rayleigh-Bénard convection (Spiegel 1962) is present also in the compressible case.

4. Conclusions

Convective energy transport and flow statistics are sensitive to the SGS Prandtl number in the parameter range currently accessible to numerical simulations. The most striking effect is the decrease of net energy transport due to downflows with decreasing Prandtl number. This happens because the oppositely signed enthalpy and kinetic energy fluxes both increase in the downflows, leading to increased cancellation (Cattaneo et al. 1991). Another effect of a decreasing Prandtl number is the increase of the overall velocity which is dominantly due to the increase of the downflow strength. The stronger downflows also lead to much stronger overshoots at the base of the CZ for lower Prandtl number.

On the other hand, the effect of the Prandtl number are very subtle in the statistics of the velocity field. The clearest systematic effect is that the filling factor of downflows decreases monotonically with decreasing SGS Prandtl number. However, the power spectra of velocity show very small differences apart from the deep layers where the downflow dominance in the low-Prandtl number regime becomes more prominent. The current results do not indicate a decrease of the large scale velocity power neither with decreasing Prandtl nor with increasing Rayleigh numbers. Such decrease has been suggested to be at least a partial solution to the convective conundrum, or the too high large-scale power in simulated flows (Featherstone & Hindman 2016). In the current simulations the large-scale power is almost unaffected most likely because the SGS entropy diffusion does not contribute to the mean energy flux unlike in the simulations of Featherstone & Hindman (2016). Notably, however, the dominant spatial scales of enthalpy and kinetic energy fluxes vary systematically with $Pr_{SGS}$ which is likely to hold the key to understanding the changing convective dynamics.

The implications of the current results of solar and stellar convection are difficult to assess because of the greatly differing parameter regimes of the simulations compared to stellar CZs. Another aspect is that the current simulations are very likely not in an asymptotic regime such that the results show a dependence on the Reynolds and Péclet numbers. Nevertheless, even with these reservations, it appears likely that convection in the Sun is quite different from that obtained from simulations in which $Pr \approx 1$. In particular, the overshooting depth can be substantially underestimated by the current simulations. It is also unclear how the Prandtl number effects manifest themselves in angular momentum transport which has thus far been only discussed in the $Pr \gtrsim 1$ regime (Karak et al. 2018).

The current simulations use SGS diffusion for the entropy fluctuations which is solely because of numerical convenience. The use of SGS diffusion has been criticized because it has no physical counterpart and as a possible cause for unrealistically strong energy fluxes in the downflows. Addressing these questions with simulations where the SGS diffusion is absent will be presented elsewhere.

Acknowledgements. I thank Axel Brandenburg and Nishant Singh for their comments on the manuscript. I acknowledge the hospitality of Nordita during the program ‘The Shifting Paradigm of Stellar Convection: From Mixing Length Concepts to Realistic Turbulence Modelling’. The simulations were made within the Gauss Center for Supercomputing project ‘Cracking the Convective Conundrum’ in the Leibniz Supercomputing Centre’s SuperMUC-NG supercomputer in Garching, Germany. This work was supported by the Deutsche Forschungsgemeinschaft Heisenberg programme (grant No. KA 4825/2-1).

\(^3\) In earlier studies of non-rotating hydrodynamic convection (Käpylä et al. 2017; Käpylä 2019b) the total force on the downflows was found to adhere closely to $\Delta \nabla$. These analyses, however, contain an error due to which the contribution from the viscous force is underestimated by a factor roughly between two and 30 depending on the depth in the CZ. Thus the agreement between $\Delta \nabla$ and $f_z$ in these earlier studies is poorer than reported and comparable to that presented in the current study.
