ABSTRACT
Recent advances in N-body simulations of dark matter haloes have shown that three-parameter models, in particular the Einasto profile characterized by $d\ln \rho(r)/d\ln r \propto r^\alpha$ with a shape parameter $\alpha \lesssim 0.3$, are able to produce better fits to the 3D spatial density profiles than two-parameter models like the Navarro, Frenk and White (NFW), and Moore et al. profiles.

In this paper, we present for the first time an analytically motivated form for the 2D surface mass density of the Einasto family of dark matter haloes, in terms of the 3D spatial density parameters for a wide range of the shape parameter $0.1 \leq \alpha \leq 1$. Our model describes a projected (2D) Einasto profile remarkably well between 0 and $(3 - 5) r_{200}$, with errors less than 0.3 per cent for $\alpha \leq 0.3$ and less than 2 per cent for $\alpha$ as large as 1. This model (in 2D) can thus be used to fit strong and weak lensing observations of galaxies and clusters whose total spatial (3D) density distributions are believed to be Einasto-like. Further, given the dependence of our model on the 3D parameters, one can reliably estimate structural parameters of the spatial (3D) density from 2D observations.

We also consider a Sersic-like parametrization for the above family of projected Einasto profiles and observe that fits with a Sersic profile are sensitive to whether one fits the projected density in linear scale or logarithmic scale and yield widely varying results. Structural parameters of Einasto-like systems, inferred from fits with a Sersic profile, should be used with caution.

Key words: gravitational lensing – galaxies: clusters: general – galaxies: fundamental parameters – galaxies: haloes – galaxies: structure – dark matter.

1 INTRODUCTION
Gravitational lensing signatures are a response to the projected surface mass column density of matter $\Sigma(\vec{R})$ along the line of sight in galaxies and clusters. Upon a suitable deprojection and circular averaging, an estimate of $\Sigma(\vec{R})$ can, in principle, be used to trace the spherically averaged 3D density profile $\rho(r)$.

In the past few years, N-body simulations have shown that three-parameter models, especially the Einasto (Einasto 1965) profile and the Sersic (Sersic 1968) profile, are able to produce better fits to the 3D density profiles of galaxy and cluster-sized dark matter haloes than two-parameter models (Navarro, Frenk and White (1997) & (1996) (NFW), Moore et al (1999)). While the PS97 profile has a well known 2D sky projected form - the Sersic (Sersic 1968) profile, there has been no such analytical counterpart for the Einasto profile.

In this paper, we present a very good approximation for the 2D projection of the Einasto family of 3D profiles. Thus, if the 3D total mass density is believed to be Einasto-like, our model can be used to parametrically describe the projected 2D surface density distributions of galaxies and clusters in the weak and strong lensing regimes. However, note that even upon radial averaging to smooth out the substructure, not all haloes subscribe to an Einasto profile. For the rest of this paper, we will limit the discussion to the 2D projection of the special case where the 3D profile is Einasto-like.

In 3D, the functional form of the Einasto (Einasto 1965) profile is given by:

$$\ln \left[ \frac{\rho(r)}{\rho_s} \right] = -b \left( \frac{r}{r_s} \right)^\alpha - 1 \quad (1.1)$$

where, $\rho(r)$ is the 3D (spatial) density at $r$, $n$ (or $\alpha = \frac{1}{n}$) is the shape parameter, $b$ is a function of $n$, $\rho_s$ the spatial density at a scale radius $r_s$, and $\rho(0) = \rho_s e^b$.

In 2D, the Sersic (Sersic 1968) profile, which has been used to describe the projected surface brightness profiles of galaxies, is similar in form to the Einasto profile in 3D (1.1) and is given by:

$$\ln \left[ \frac{\Sigma_S(R)}{\Sigma_{RE}} \right] = -q \left( \frac{R}{R_E} \right)^\alpha - 1 \quad (1.2)$$

such that $\Sigma_S(0) = \Sigma_{RE} e^q$, where, $R$ is the projected distance in
the plane of the sky, $\Sigma_{RE}$ is the line of sight projected surface brightness at a projected scale radius $R_E$, which can be defined to be the half-light radius of a Sersic profile under the condition: $q = 2m - 0.3333 + 0.0009876/m$ (PS97) with $m$ (or $\lambda = 1/m$) characterizing the shape of the Sersic profile.

The parameter $\alpha = -2$ in (1.1) defines the shape of the Einasto profile. In the first ever fits to N-body haloes with a Einasto profile, Nav04 found an average value of 0.172±0.032 for a wide range of halo masses from dwarfs to clusters. For galaxy-sized haloes Prada et al. (2006) found $0.133 \leq \alpha \leq 0.167$. Harashita and White (2008) observed an evolution of $\alpha$ with mass and redshift ($z$) in the Millennium Simulation (MS) of Springel et al. (2005) and found $\alpha \sim 0.17$ for galaxy and $\sim 0.23$ for cluster-sized haloes. A similar trend is supported by Gao et al. (2008) where $\alpha \sim 0.3$ for the most massive clusters in MS. Hence, although in this paper we discuss our approximation to a projected Einasto profile for $0.1 \leq \alpha \leq 1$, particular attention is drawn to the domain $\alpha \leq 0.3$; where as we shall show in §3, the errors due to our approximation out to 30$r_{200}$ ($\sim (3 - 5)r_{200}$) are $< 0.3\%$.

The parameters $r_s$, $b$, and $n$ in the Einasto profile are not independent. It can be seen, that in terms of a dimensionless length $X = r/r_s$, the logarithmic slope of the density profile is given by:

$$\beta = \frac{d \ln(\rho/\rho_s)}{d \ln X} = -\frac{b}{n} X^{1/n} \tag{1.3}$$

Nav04 chooses to define $r_s$ such that $b/n = 2$ (the isothermal value of $\beta = -2$) at $r = r_s$ and hence label $r_s$ as $r_{200}$ and $\rho_s$ as $\rho_{200}$. Another approach is to use the convention of M06, requiring $r_s$ to include half the total mass. They quote a numerical estimate of $b=3n - 0.333 + 0.0079/n$. In this paper we will follow the Nav04 parametrization.

Since the Sersic profile describes the 2D surface brightness profiles of galaxies reasonably well, a natural question is: does the 2D surface mass density of Einasto-like 3D dark matter haloes also follow a Sersic-like description? For the Nav04 simulations, Merritt et al. (2005) have shown that a deprojected Sersic profile also fits the 3D distributions almost as well as the Einasto profile, and a Sersic profile fits the non-parametrically estimated 2D surface densities of dark matter haloes with acceptable errors ($\sim 5\%$ per cent).

In the following discussion, we argue that if a 3D distribution is Einasto-like, the 2D distribution need not be Sersic-like and provide an analytically motivated functional form for the 2D projection, which can be used to describe the surface mass density of the Einasto family of dark matter haloes subscribing to a wide range of the shape parameter ($1 \leq n \leq 10$ or $0.1 \leq \alpha \leq 1$) and over a wide radial (projected) range $0 \leq R \leq 6 r_{200}$.

### 2 SURFACE MASS DENSITY OF THE EINASTO PROFILE

The Einasto profile has generated considerable interest of late and has been used in recent studies of dark matter haloes (Nav04, Pr06, M06, G08, HW08, S09). For the N-body haloes in Nav04, Merritt et al. (2005) have shown that within the limited radial range of $r_{conv} \leq r \leq r_{200}$ and shape parameter $0.12 \leq \alpha \leq 0.22$, a deprojected Sersic profile also fits the 3D distributions almost as well as the Einasto profile, and a Sersic profile fits the non-parametrically estimated 2D surface densities of dark matter haloes with acceptable errors ($\sim 5\%$ per cent).

In terms of the line of sight distance ($z$), the surface mass density $\Sigma(R)$ can be estimated from:

$$\Sigma(R) = 2 \int_0^\infty \rho(\sqrt{z^2 + R^2})dz \tag{2.1}$$

While an exact analytical expression for the integral in (2.1) for the Einasto profile (1.1) has so far eluded us, we derive below an excellent semi-analytical approximation.

To intuitively motivate the functional form of $\Sigma_E(R)$ for the Einasto profile (1.1), observe that at $R = 0$, the integral (2.1) presents us with an exact solution:

$$\Sigma_E(0) = \frac{2e^b r_s n \rho_s}{b^n} \Gamma[n] \tag{2.2}$$

where, $\Gamma[n]$ is the complete Gamma Function.

Hence, for $R > 0$, it is reasonable to expect the integral to depend on terms involving incomplete gamma functions. In fact, for the sake of discussion, one can make a very crude assumption that most of the contribution to the integral in (2.1) at a given $R$ (especially for $R < r_{200}$) comes from the region $z > R$. Integrating, from some $\zeta R \to \infty$ (where $\zeta > 1$), one gets:

$$\Sigma(R) = \frac{2e^b r_s n \rho_s}{b^n} \Gamma[n, b(\zeta R/r_s)] \tag{2.3}$$
Similarly, the integral for $R > r_{-2}$ will have dominant contributions from terms involving $\gamma [a, z]$; where $\Gamma [a, z]$ and $\gamma [a, z]$ are the upper-incomplete and lower-incomplete gamma functions respectively.

This is quite unlike a Sersic (1.2) function. Hence, although a Sersic profile may fit a projected Einasto profile in a limited range of $R$ it need not be a very good fit for all $R$.

### 2.2 $\Sigma_E(R)$: An analytical approximation of projected Einasto profile

With the 3D spatial distance $r = \sqrt{z^2 + R^2}$, where $R$ is the 2D projected distance in the plane of the sky, and $z$ the line of sight distance from the object to the observer, at any given $R$, one can define 3 regions for the integral in (2.1) for the Einasto profile (1.1).

Region I: $z < R$, integrating from $z = 0$ to $\zeta R$, with $\zeta_1 \leq 1$

Region II: $z > R$, integrating from $z=\zeta_2 R$ to $\infty$, with $\zeta_2 > 1$, and Region III: $z \sim R$, in a neighborhood $\delta$ between $\zeta_1 R$ and $\zeta_2 R$

In Region I: $z < R$, the first term on the right hand side (RHS) of (1.1) can be written as:

$$-b \left( \frac{z^2 + R^2}{r^2} \right)^{\frac{n}{2}} = -b \left( \frac{R}{r} \right)^{\frac{n}{2}} \left[ 1 + \left( \frac{z}{R} \right)^2 \right]^{\frac{n}{2}}.$$

Neglecting 4th and higher order terms in $(z/R)$, in the binomial expansion of (2.4), the integral of (2.1) (from $z = 0$ to $\zeta_1 R$) has an analytical approximation:

$$\rho_\ast r_s \exp \left[-b \left( \frac{1}{\zeta_1} \right)^{\frac{n}{2}} \right] \sqrt{\frac{2n}{b} \left( \frac{R}{r_s} \right)^{(1 - \frac{n}{2})}} \times \gamma \left[ \frac{1}{2} \zeta_1^{\frac{b}{2n}} \right] \left( \frac{R}{r_s} \right)^{\frac{n}{2}}.$$

In Region II: $z > R$, a binomial expansion of the first term of the RHS of (1.1) gives us:

$$-b \left( \frac{z}{r_s} \right)^{\frac{n}{2}} (1 + \frac{R}{z})^{\frac{n}{2}} = -b \left( \frac{R}{r_s} \right)^{\frac{n}{2}} \left[ \frac{1}{2n} \left( \frac{R}{z} \right)^{2 - \frac{n}{2}} + ... \right]$$

Fits to N-body simulations with the Einasto profile have so far indicated an $n > 3.0$ ($\alpha \approx 0.3$). Hence, observing that the leading contribution comes from the 1st term $b(z/r_s)^{\frac{n}{2}}$, one can drop the remaining terms. This is especially true in our primary domain of interest ($3 \leq n \leq 10$, i.e. $\alpha \leq 0.3$). Even for $1 \leq n < 3$, although the approximation is not as good as it is for $n \geq 0$, it continues to provide better fits than a Sersic profile in the entire range $1 \leq n \leq 10$. With this understanding, the integral from $z = \zeta_2 R$ to $\infty$, in Region II can be written as:

$$\frac{2b^2 r_s n \rho_\ast}{b^n} \Gamma \left[ n, b \left( \frac{\zeta_2 R}{r_s} \right)^{\frac{n}{2}} \right].$$

In Region III: $\zeta_1 R \leq z \leq \zeta_2 R$, one can not make the same approximations made in regions I and II. However, there exists a point $\epsilon R$ between $\zeta_1 R$ and $\zeta_2 R$, where the mean-value approximation will be valid in a domain $\delta$ about $\epsilon R$. Since the density profile falls rapidly for $R << r_{-2}$ and gradually for $R >> r_{-2}$, the domain of applicability of the mean-value approximation will be such that $\delta < (\zeta_2 - \zeta_1)$ for $R < r_{-2}$ ($\to 0$ as $R \to 0$) and tending to $\zeta_2 - \zeta_1$ for $R >> r_{-2}$. Further, it should be obvious that $\zeta_1, \zeta_2$ and $\delta$ will depend on the shape parameter $n$ as well. A function describing $\delta$, with such a property is:

$$\delta = (\zeta_2 - \zeta_1) \left[ 1 - \exp(-\epsilon^{2}\rho(R/r_s)^n) \right]$$

with $\mu = \mu(n)$

The remaining (small) excluded region does not add significantly to the integral (refer to error plots in §3).

With this, the contribution to the integral in (2.1), from region III- a domain $\delta$ around $R$ - from an application of the mean-value theorem at $\epsilon R$ can be written as:

$$2\delta R \rho(z = \epsilon R) = 2\delta R \rho_s \exp \left(-b \left[ \frac{\sqrt{1 + \epsilon^2 R^2}}{r_s} \right]^{\frac{n}{2}} - 1 \right).$$

A few important observations are in order. First, neglecting terms in the integrand of region I (2.3) and II (2.5), leads to overestimating the integrands in those regions. Second, ignoring the contribution from region III and fitting only for $\zeta_1$ and $\zeta_2$, produces good fits (refer to discussion following (2.13)) but understandably with a $\zeta_2$ greater than $\zeta_2$ with region III included. i.e. including region III, lowers $\zeta_2$ allowing it to be closer to 1, resulting in a larger contribution from the upper-incomplete gamma function. A simultaneous fit of $\zeta_1, \zeta_2, \epsilon$ and $\mu (in \delta)$ accounts for these excess contributions through a negative sign from region III.

In region I, since $4^{th}$ and higher order terms in $z/R$ are neglected, one can fix $\zeta_1 = 1$. Further, although $\epsilon$ should in principle be estimated, we found it to be a reasonable approximation to fix $\epsilon = \frac{\zeta_2 - \zeta_1}{4}$. This reduces the number of parameters to fit to only two - $\zeta_2$ and $\mu$ - which in turn, during the fitting process, compensates for the approximations made on $\zeta_1$ and $\epsilon$.

With these approximations, the surface mass density $\Sigma_E(R)$, for $1 \leq n \leq 10$ with $X = R/r_s$ can be written as:

$$\Sigma_E(R) = \frac{\Sigma_{E_0}}{\Gamma(n + 1)} \left[ n \Gamma \left[ n, b \left( \zeta_2 X \right)^{\frac{n}{2}} \right] \right]$$

$$+ \frac{b^n}{2} \sqrt{\frac{2n}{b}} X^{-\frac{1}{2n}} \gamma \left[ \frac{1}{2} \zeta_1 \frac{b}{2n} X^{\frac{1}{2n}} \right] e^{-bX^{\frac{1}{2n}}},$$

where,

$$\Sigma_{E_0} = \Sigma_E(0) = \frac{2b^2 r_s n \rho_\ast \Gamma(n + 1)}{b^n}.$$

For the Nav04 parametrization of $\frac{\zeta_2 - \zeta_1}{4} = 1$ and by choosing $\zeta_1 = 1$, (2.11) simplifies to (2.11), where, after substituting factors like $b/2n$ with 1 in (2.11), we leave $b$ in the rest of the equation in order to reduce clutter. This gives us:

$$\Sigma_E(R) = \frac{\Sigma_{E_0}}{\Gamma(n + 1)} \left[ n \Gamma \left[ n, b \left( \zeta_2 X \right)^{\frac{n}{2}} \right] \right]$$

$$+ \frac{b^n}{2} X^{-\frac{1}{2n}} \gamma \left[ \frac{1}{2} \zeta_1 \frac{b}{2n} X^{\frac{1}{2n}} \right] e^{-bX^{\frac{1}{2n}}} - \delta b^n X^{-\frac{1}{2n}} e^{-\sqrt{1 + \epsilon^2 X^{\frac{1}{2n}}}}$$

with,

$$\delta = (\zeta_2 - \zeta_1) \left[ 1 - e^{-\epsilon^2 \rho(R/r_s)^n} \right]$$

$$\epsilon = \frac{\zeta_2 - \zeta_1}{2}$$
Figure 1. $\zeta_2(n)$ for $0.1 \leq \alpha \leq 1.0$ (1.0 $\leq n \leq 10.0$). Each point has been obtained by fitting the numerically projected Einasto profile with (2.11) for $b = 2n$ and $\zeta_1 = 1$.

$\zeta_1 = 1$

$\zeta_2 = 1.1513 + \frac{0.05657}{n} - \frac{0.00203}{n^2}$

$\mu = 1.5096 + \frac{0.82505}{n^2} - \frac{0.66290}{n^3}$

Figure 2. $\mu(n)$ for $0.1 \leq \alpha \leq 1.0$ (1.0 $\leq n \leq 10.0$). Each point has been obtained by fitting the numerically projected Einasto profile with (2.11) for $b = 2n$ and $\zeta_1 = 1$.

3 COMPARISON WITH NUMERICALLY PROJECTED EINASTO PROFILES

3.1 Estimating $\zeta_2$ and $\mu$ for $\Sigma_E$

We numerically integrate (2.1) for the profile in (1.1) and obtain $\Sigma_N(R)$ in the domain $R : (0 - 30) \ r_{-2}$ for 90 profiles with a shape parameter in the range $0.1 \leq \alpha \leq 1.0$. A resolution in $R$ of 0.002 $r_{-2}$ ($\sim 0.05 \ r_{\text{conv}}$), allows us to quantify errors due to our approximation in a domain $R < r_{\text{conv}}$, and we report comparison of errors up to $30 \ r_{-2}$ or up to a $R$ where $\Sigma_N(R) \sim 10^{-8} \Sigma(0)$ whichever is earlier.

With $b = 2n$ and $\zeta_1 = 1$, we use a non-linear least squares Levenberg-Marquardt algorithm to estimate the best-fitting values for $\zeta_2$ and $\mu$ by fitting (2.11) to each of the numerically generated $\Sigma_N$ profiles. We find that $\zeta_2$ and $\mu$ are best described by a second and third degree polynomial respectively, in $\alpha = 1/n$ (Fig.1 and Fig.2).

3.2 A detailed look at errors in the $\Sigma_E$ approximation

Fig. 3 and Fig. 4 describe the fractional error profile between our model $\Sigma_E$ and the numerically projected Einasto profile $\Sigma_N(R)$ for a wide range of the shape parameter $\alpha = 1/n$. Fig. 3 is more relevant to current N-body simulations, where in $\alpha$ seems to be in the range 0.1 to 0.25. It is worth noting here, that for $\alpha$ as high as 0.25 ($\alpha = 4.00$), the largest errors are $< 0.3\%$ in the range (0 to 30) $r_{-2}$.

In case the range $1 \leq \alpha \leq 3$ becomes relevant in the future, where N-body haloes for $\alpha \geq 0.4$ have not yet been found, we also present in Fig. 4 a comparison between $\Sigma_E$ and $\Sigma_N$. This is also the domain where our assumptions in the $z > R$ region are weaker. Nevertheless, the accuracy of the approximation is striking with the worst error $< 1\%$ within $R < 5 \ r_{-2}$.

3.3 Comparison with Sersic profiles

In this section we discuss results of fits to $\Sigma_N$ with a Sersic function and superimpose the $\Sigma_E$ model (black solid lines) (2.11) for a relative comparison between $\Sigma_E$ and $\Sigma_N$ (Fig. 5 and Fig. 6). The fits presented here were obtained using log scale of density. One can also obtain fits with density in linear scale; a comparison of...
residuals for the case $\alpha = 0.17$ is presented in Fig. 7. The best fit parameters and consequently the error profile are quite different and an indication that the best-fitting Sersic profile does not provide an adequate representation of a projected Einasto profile.

Not evident in the plots (Fig. 5-7) are the extremely large errors in the central density $\Sigma_S(0)$ when fitting using log density. For $\alpha = 0.1$ (Fig. 5) the relative error at $R = 10$ is $375\%$, for $\alpha = 0.17$ (Fig. 5 and 7), the relative error is $215\%$ and $33\%$ for $\alpha = 1$. However, we observed empirically that fits in log density happen to reflect the significance of $R_E$ as enclosing half the total mass of $\Sigma_N$ (it is to be noted that $R_E$ by definition encloses half the total mass of $\Sigma_N$). This is because the domain over which $\Sigma_S$ (with fits obtained in log density) overestimates the density is a relatively small contributor to the total mass and fits with log density in the region $R > r_{-2}$ are good. Since, we can reliably estimate one of the Sersic profile parameters ($R_E$) through fits with log density (as opposed to none in linear scale), we have presented results of fits in log density in Fig. 5 and Fig. 6.

The large errors in the central density also have serious consequences for strong lensing. Typically the strong lensing regime extends up to $\sim 0.1 r_{-2}$. In strong lensing, image positions correspond to extremum (minima, maxima and saddle) points of the time delay surface. The $j^{th}$ image position $\theta_i$ for the $i^{th}$ source $\beta_i$ is given by:

$$\bar{\theta}_{ij} = \beta_i + \frac{1}{\pi} \int \frac{(\bar{\theta}_{ij} - \bar{\theta}) \kappa(\bar{\theta})}{|\bar{\theta}_{ij} - \bar{\theta}|^2} d\theta'$$

(3.1)

where $\kappa(\bar{\theta})$ is the normalized surface mass density at an angular position $\bar{\theta}$.

Consequently contributions to the integral in (3.1) from unusually large density near the center (as a result of fits with a Sersic profile in log density), will produce image separations larger than what one can expect from a numerical projection of the 3D Einasto profile.

Sersic profile fits to model a projected Einasto profile should thus be avoided especially if the central region ($R < 0.1 r_{-2}$) is being excluded. This is because, as shown in Fig. 7, one can get a reasonably good fit (relative error within $10\%$) over a large range of $R < 0.1 r_{-2}$ (fitting in log density) giving an indication that the Sersic profile is a good representation of projected Einasto profile, but doing so will lead to even larger errors in the excluded central region ($R < 0.1 r_{-2}$). One should thus use caution in interpreting the other structural parameters, the shape parameter $m$ or $\lambda$ and the central density $\Sigma_S(0)$.

In fits linear density present a different problem. Even though the central errors are much better (relative error $\sim 10\%$ for $\alpha = 0.17$, Fig. 7) than fits using log density, the best-fitting $R_E$ does not enclose half the total mass of $\Sigma_N$ and the errors for large $R$ keep increasing with $R$.

Although the Sersic profile is not a good representation of a projected Einasto profile, one can fit Sersic profiles in limited domains of $R$ and obtain an estimate of the shape of the projected Einasto profiles in those domains only, but be careful to not use the resulting best-fitting values of $R_E$ and $\Sigma_S(0)$ as a true representation of the half-mass radius and central density of the projected Einasto. In Fig. 8, we present two such relations between the 2D projected radius $R$ and the 3D scale radius $r_{-2}$ of the corresponding Einasto profile. $r_{200} \sim 6 r_{-2}$ while $r_{conve} \sim 0.05 r_{-2}$.

\begin{equation}
\lambda(\alpha) = 1.332 \alpha^{0.741}
\end{equation}

(3.2)

and for $R > r_{-2}$ defined as in §3.1:

\begin{equation}
\lambda(\alpha) = 1.037 \alpha^{0.882}
\end{equation}

(3.3)

Not only is the shape ($\lambda$) different in the two domains, their evolution with $\alpha$ is also different. Nevertheless, this result can be useful in obtaining an estimate of the shape of projected Einasto profile in these two domains demarcated by $r_{-2}$.

The $\Sigma_E$ model, with errors $< 0.5\%$ does not face any of the above issues. Further, unlike the Sersic profile, the $\Sigma_E$ model can predict the central density with almost $0\%$ errors due to the existence of an analytical solution. Thus, if the underlying 3D distribution is Einasto-like, the 2D distribution should be modeled with $\Sigma_E$.

### 3.4 Extracting the 3D-parameters from the $\Sigma_E$ model

The $\Sigma_E$ model is not just a good description of the projected Einasto profile but is also expressed in terms of the 3D Einasto...
Einasto index

Figure 6. Fractional Error between the best-fitting $\Sigma_S$ and $\Sigma_N$ with Einasto index $0.1 \leq \alpha \leq 0.25$, $4 \leq n \leq 10$ with fractional error for the best-fitting $\Sigma_E$ (black solid lines $\approx 0$) superimposed. The $x$-axis plotted in log scale is expressed as a ratio of the 2D projected radius $R$ and the 3D scale radius $r_{-2}$ of the corresponding Einasto profile. $r_{200} \sim 6 r_{-2}$ while $r_{\text{conv}} \sim 0.05 r_{-2}$.

Figure 7. Fractional Error in $\Sigma_S$ from fits to $\Sigma_N$ (for $\alpha = 0.17$) with a Sersic profile using log density (dot-dashed line) and a Sersic profile using linear density (dashed line). Not shown in the plots are the errors in central density $\Delta \Sigma_S(0)$. The errors are 215% for the fit with log density and 10% for the fit with linear density. The fractional error in $\Sigma_E$ (black solid line $\approx 0$) is superimposed for comparison. The $x$-axis, plotted in log scale, is a ratio of the 2D projected radius $R$ to the 3D scale radius $r_{-2}$ of the corresponding Einasto profile. $r_{200} \sim 6 r_{-2}$ while $r_{\text{conv}} \sim 0.05 r_{-2}$.

Figure 8. Sersic index $(\lambda=1/m)$ of a projected (2D) Einasto profile as a function of the 3D Einasto index $(\alpha=1/n)$ in two domains $R < r_{-2}$ (dotted) and $R > r_{-2}$ (solid) indicating the absence of a unique Sersic index $\lambda$ for all $R$. The power law relations for $\lambda(\alpha)$ in equations 3.2 and 3.3 are applicable only in these domains.

profile parameters. It should thus be possible to recover the 3D parameters $(\alpha, r_{-2}, \rho_{-2})$ from fits to 2D distributions that subscribe to an underlying 3D Einasto-like system.

For the wide family of numerically projected Einasto profiles $\Sigma_N$ described in this paper, we could recover the 3D parameters for all of them with an accuracy of $\sim 10^{-3}$ or better, by fitting $\Sigma_N$ with (2.11) and the parametrizations of (2.12) and (2.13) through a non-linear least squares Levenberg-Marquardt algorithm. Given that, as of now robust data (within virialized regions) from N-body simulations are in the domain $r_{\text{conv}} \sim r_{200}$, the fits were performed in this domain. In passing, we note that our results are even better if we fit from 0 to 30 $r_{-2}$. Such a high degree of accuracy indicates that if the 2D distribution is indeed a projected Einasto profile, the 3D parameters can be recovered very well even from a limited radial range of observations.

We note that, for the entire range of $0.1 \leq (\alpha = \frac{1}{n}) \leq 1$ the fits always converged for an initial guess of $\alpha < \text{true} \alpha$, $r_s > \text{true} r_{-2}$ and $\rho_{-2}$ in the range (0.1 to 4) $\rho_{\text{true}}$. An initial guess of very low $\alpha \sim 0.05$ and a guess for $r_{-2} \sim r_{200}$ for the type of object (galaxy or cluster) being considered can be a reasonable starting value for the fit to converge. We also did not encounter any local minima. i.e. if the fit converges, it always converged to the true set of $(\alpha, r_{-2}, \rho_{-2})$.

4 SUMMARY AND CONCLUSIONS

Non-parametric estimates of density profiles in N-body simulations (Nav04, M06) favour Einasto-like profiles, since they provide better fits than the two-parameter NFW and Moore profiles. Merritt et al. [2006] have also shown that a de-projected Sersic pro-
Surface mass density of the Einasto family of dark matter haloes: Are they Sersic-like?

7

file fits the 3D halo mass distribution almost as well as the Einasto profile, and a Sersic profile provides good fits to non-parametric estimates of surface mass densities (M05) of the Nav04 N-body haloes.

We have observed that fits with a Sersic function ($\Sigma_S$) to a numerically projected Einasto profile ($\Sigma_N$) are sensitive to whether one fits using linear density $\Sigma_S$ (errors increasing for large R) or log density $\ln(\Sigma_S)$ (errors increasing for small R) yielding widely varying results. Consequently, the Sersic profile does not give an adequate description of the projected Einasto profile.

Sersic profile fits to the surface mass density of N-body haloes (M05), whose 3D spatial densities are well fit by Einasto profiles with $0.12 \leq \alpha \leq 0.22$, have been obtained from the limited radial range of $r_{conv}$ to $r_{200}$. For the haloes in M05 and Nav04, this range is generally less than two decades in radius. Hence, if the 3D distribution is indeed Einasto-like, interpreting structural properties from fits with a Sersic profile, especially $m$ in $\Sigma_S(0)$ as the central density and $R_E$ as the half-mass radius, can be misleading.

In this paper, we have provided an analytical approximation (2.11) to the projected surface mass density of Einasto-like 3D density distributions. The fit errors are well contained to $\leq 2\%$ for the projected radial range $0 \leq R \leq (10 - 30)$ $r_{200}$ equivalent to $(3 - 5)r_{200}$ and shape parameter, $1 \leq n \leq 10$, or $0.1 \leq \alpha \leq 1$. This model can therefore be used both as a fitting function for 2D observations and also to extract the 3D parameters of Einasto-like profiles. Since $\Sigma_E$ fits a projected Einasto profile in a wide radial range, it can be used for fitting strong and weak lensing observations in systems whose total 3D density distribution is believed to be Einasto-like. One can also numerically integrate (2.11) to get reliable estimates of the mass enclosed.

Finally, we note that the form similarity of (1.1) and (1.2), i.e. fitting functions that describe the 3D mass density of dark matter haloes and the 2D light distributions of galaxies, respectively, could be largely coincidental and should be used with caution when drawing conclusions about the similarity of dynamical evolution that lead to the formation of the stellar components of ellipticals and dark matter haloes.
