Laminarinase from \textit{Flavobacterium} sp. reveals the structural basis of thermostability and substrate specificity

Hui-Min Qin\textsuperscript{1,2}, Takuya Miyakawa\textsuperscript{1}, Akira Inoue\textsuperscript{3}, Akira Nakamura\textsuperscript{3}, Ryuji Nishiyama\textsuperscript{3}, Takao Ojima\textsuperscript{3} & Masaru Tanokura\textsuperscript{1,2}

Laminarinase from \textit{Flavobacterium} sp. strain UMI-01, a new member of the glycosyl hydrolase 16 family of a marine bacterium associated with seaweeds, mainly degrades \(\beta\)-1,3-glucosyl linkages of \(\beta\)-glucan (such as laminarin) through the hydrolysis of glycosidic bonds. We determined the crystal structure of ULam111 at 1.60-Å resolution to understand the structural basis for its thermostability and substrate specificity. A calcium-binding motif located on the opposite side of the \(\beta\)-sheet from catalytic cleft increased its degrading activity and thermostability. The disulfide bridge Cys31-Cys34, located on the \(\beta_2\)-\(\beta_3\) loop near the substrate-binding site, is responsible for the thermostability of ULam111. The substrates of \(\beta\)-1,3-linked laminarin and \(\beta\)-1,3-1,4-linked glucan bound to the catalytic cleft in a completely different mode at subsite -3. Asn33 and Trp113, together with Phe212, formed hydrogen bonds with preferred substrates to degrade \(\beta\)-1,3-linked laminarin based on the structural comparisons. Our structural information provides new insights concerning thermostability and substrate recognition that will enable the design of industrial biocatalysts.

Glucans with \(\beta\)-1,3-linkages are widely distributed in nature and are found in bacteria, fungi, plants, and algae. \(\beta\)-1,3-linked glucan is the main constituent of botanical and fungal cell walls; it is a major structural polysaccharide\textsuperscript{4}. Laminarin is a storage polysaccharide of marine macroalga\textsuperscript{5,6}. Its main chain consists of glucose with \(\beta\)-1,3-linkages and partial branches connected through \(\beta\)-1,6-linkages. Ratios of \(\beta\)-1,3- and \(\beta\)-1,6-linkages are diverse, e.g., 7:1 in \textit{Laminaria digitata} and \textit{L. hyperborea}\textsuperscript{3} and 3:2 in \textit{Eisenia bicyclis}\textsuperscript{3}. Laminarin has shown anti-apoptotic and anti-tumor activities\textsuperscript{5,6}. Laminarin is also a potential source of fermentable sugars for bioethanol production\textsuperscript{7}. Therefore, it has received attention in the design of biocatalysts for the development of a cost-competitive process for converting laminarin into fermentable sugar for the widespread utilization\textsuperscript{8,9}. Some other extracellular polysaccharides, such as curdlan and lichenin, have also been demonstrated to be non-toxic, and have applications in the food and pharmaceutical industries\textsuperscript{10}. Curdlan is unbranched and consists of glucosyl residues that are linked by \(\beta\)-D-1,3 bonds with its degree of polymerization being about 135 glucose residues\textsuperscript{11}. Lichenin could form symbiotic relationships with algae in lichens has a ratio of \(\beta\)-D-1,4-glucopyranosyl to \(\beta\)-D-1,3-glucopyranosyl residues of 2.3:1 in \textit{Cetraria islandica}\textsuperscript{12}.

Laminarinas (EC 3.2.1.6, known as \(\beta\)-1,3-glucanohydrolase or \(\beta\)-1,3-glucanase) catalyzes the hydrolysis of 1,3- and 1,4-linkages in \(\beta\)-D-glucans\textsuperscript{13}. Laminarinase can play various physiological roles in bacteria, viruses, and plants\textsuperscript{14,15}. In bacteria, laminarinases are classified into exo-\(\beta\)-1,3-glucanases (EC 3.2.1.58) and endo-\(\beta\)-1,3-glucanases (laminarinase; EC 3.2.1.39), which share high sequence similarity to endo-\(\beta\)-1,3-1,4-glucanases (EC 3.2.1.73). Exo-/endo-\(\beta\)-1,3-glucanases hydrolize \(\beta\)-1,3-glucans such as laminarin and release glucose residues or oligosaccharides, while endo-\(\beta\)-1,3-1,4-glucanases may also hydrolyze polysaccharides.
containing β-1,4 linkages, such as lichenin. Therefore, both laminarinases and β-1,3-1,4-glucanases are expected to become promising biocatalysts in the generation of biochemicals and bioenergy.

The Carbohydrate-Active Enzymes database (CAZy; http://www.cazy.org) provides a sequence-based family classification linking the sequence to the specificity and 3D structure of the enzymes, in which most bacterial laminarinases and β-1,3-1,4-glucanases belong to the GH16 family. Some members of this family have been characterized, and crystal structures have been analyzed for enzymes from Thermotoga maritima, hyperthermophile Pyrococcus furiosus, Nocardiopsis sp. strain F96, and Zobellia galactanivorans. It is not easy to classify GH16 family enzymes aside from a classical sandwich-like β-jelly roll fold composed of two antiparallel β-sheets packed against each other. Determining the crystal structures of laminarinases/glucanases provides useful examples of versatile yet specific protein-carbohydrate interactions, which could not be precisely predicted by sequence alignment alone.

Flavobacterium sp. UMI-01 is a novel bacterium recently identified from decayed brown algae; it has been grown in medium containing either alginate or laminarin as a sole carbon source. Flavobacteria contains a high abundance of family GH16 laminarinases, underlying the environmental importance of decomposing algal biomass. Genomic sequence analysis revealed the presence of a candidate gene for GH16 β-1,3-laminarinase, which was designated as ULam111. This enzyme consists of 235 residues and has a molecular mass of approximately 27 kDa. Herein, we determined the crystal structure of ULam111 at 1.60-Å resolution. The structure revealed new insights concerning the thermostability and substrate recognition for the degradation of polysaccharides by the laminarinase family, which may be suitable for beer brewing and feed additives.

### Results and Discussion

#### Overall structure of ULam111.

The crystal structure of ULam111 was refined to 1.60-Å resolution. Two protein molecules and 670 water molecules were observed in the asymmetric unit of the ULam111 crystal. The R and Rfree values of the final model were 17.6 and 20.6%, respectively. In the Ramachandran plot, 97.4% of residues were included in the favored region, and 2.6% were in the allowed region. The refinement statistics are summarized in Table 1.

The overall structure of ULam111 contained two α-helices and 15 β-strands and possessed a β-jelly roll fold (Fig. 1a) that is adopted in GH16 family enzymes. The fold comprises two antiparallel β-sheets (Sheet A and Sheet B). Sheet A consists of seven β-strands (β2, residues 24–26; β5, residues 66–73; β7, residues 97–105; β8, residues 118–124; β9, residues 131–137; β10, residues 148–152; and β14, residues 200–208), and sheet B consists of seven β-strands (β1, residues 1–23; β3, residues 50–58; β4, residues 61–65; β6, residues 74–83; β11, residues 106–117; β12, residues 126–134; and β13, residues 138–200).

of eight \( \beta \)-strands (\( \beta_1 \), residues 6–11; \( \beta_3 \), residues 49–52; \( \beta_4 \), residues 55–63; \( \beta_6 \), residues 83–90; \( \beta_11 \), residues 161–167; \( \beta_12 \), residues 172–176; \( \beta_13 \), residues 179–184; and \( \beta_15 \), residues 224–235).

Characteristics of the active site. The catalytic residues included Glu118, Asp120, Glu123, and His137 (Fig. 1b). On the basis of the conserved catalytic mechanism\(^{21,28} \), Glu118 was assumed to be the nucleophile that directly attacks C1 of the sugar ring, and Glu123 was hypothesized to function as the proton donor. The interaction of Asp120 with His137 via a hydrogen bond was considered to stabilize the substrate.

Comparison of the ULam111 structure with other family enzymes. A structure homology search using Dali\(^{29} \) showed that the overall structure of ULam111 is highly similar to previously reported enzymes, including TmLam from *Thermotoga maritima* (PDB code, 3AZZ; Z-score, 34.8; r.m.s.d., 1.5 Å; sequence identity, 45%), BglF from *Nocardiopsis* sp. strain F96 (PDB code, 2HYK; Z-score, 33.8; r.m.s.d., 1.7 Å; sequence identity, 44%) and PfLamA from the hyperthermophile *Pyrococcus furiosus* (PDB code, 2VY0; Z-score, 33.8; r.m.s.d., 1.4 Å; sequence identity, 43%).

Although ULam111 shared >43% sequence identity with TmLam, BglF and PfLamA, structural determination by molecular replacement using a structure model of TmLam was not successful, indicating that there may be conformational differences between ULam111 and some family enzymes. The superposition of ULam111 with TmLam, BglF, and PfLamA showed that these proteins contained the common \( \beta \)-jelly roll folds and a straight groove for substrate binding (Fig. 2). ULam111 shared the bulging loop of \( \beta_2-\beta_3 \) with TmLam and PfLamA.

Comparison of substrate binding site. Some \( \beta \)-strands of Sheet A twisted somewhat to form an electronegative-rich cleft where the substrates were implicated to bind (Fig. S2). It is obvious that ULam111 binds \( \beta \)-1,3-linked or \( \beta \)-1,3-1,4-linked substrates in a straight catalytic cleft and cleaves the glucosidic bond in an open form because there are no additional loops covering the active site (Fig. 2a). The sugar ring may form hydrogen bonds at the negatively charged binding site of ULam111 with hydrophilic residues, such as Asn33, Gly37, Asn38, and Arg71, and hydrophobic-stacking interactions with Trp98, Trp102, and Trp113, whereas most of the residues are conserved in the GH16 family enzymes (Fig. 3a). Notably, Phe212, located above the catalytic residues of positive substrate-binding site +1, was not conserved (tryptophan in GH16 family enzymes) and showed different spatial orientations than other enzymes (Fig. 3b). It was reported to regulate substrate recognition in the release of glucose in carbohydrate hydrolysis\(^{21} \).

Thermostability of ULam111. ULam111 contained a special calcium-binding motif on the opposite side of the \( \beta \)-sheet from the catalytic cleft (Fig. 4), which was composed of His12, Asn14, Gly54, and Asp229. The calcium ion was coordinated to the carbonyl and carboxylate O atoms of Asp229, the carbonyl O atom of Gly54, and the carbonyl O atom of Asn14. This motif is known to increase thermostability in GH16 family enzymes\(^{30} \). However, the calcium-binding motif is not conserved in this family. The residues of Asn14 and His12 in ULam111 were positioned near glutamic acid and aspartic acid in other enzymes (Fig. 4). The H12E/N14D substitution could increase the degradative activity toward laminarin and thermostability from 15 °C to 40 °C (Fig. 5). It is interesting that the calcium ion could significantly increase the activity and thermostability of wild-type and
Figure 2. (a) The surface of ULam111 displaying a straight topology. The additional loop of ZgLamA is red. (b) Superposition of the structures of ULam111 (green), BglF from Nocardiopsis sp. strain F96 (salmon), TmLam (cyan), and PI LamA from hyperthermophile Pyrococcus furiosus (magenta). The disulfide linkage of Cys31-Cys34 is shown as red sticks. The black dashed cycles showed different structures between ULam111 and other GH16 family enzymes. (c) Relative activity of ULam111 mutant toward laminarin. The activity of wild-type ULam111 is represented as 100 and the error bars are standard deviations (n = 3).

Figure 3. (a) Molecular basis for the recognition of β-1,3-linked laminarin and β-1,3-1,4-linked glucans by ULam111. The β-1,3-linked laminarin and β-1,3-1,4-linked glucans are cyan and salmon colored, respectively. The amino acids in ZgLamA are yellow. (b) Comparison of spatial orientation of Phe212 (green) in ULam, Trp270 (white) in PI LamA, and Trp232 (magenta) in TmLam.
mutant enzymes. Especially at 50 °C, the enzymes retained approximately 80% activity under 1.0 mM CaCl₂. Therefore, both the mutant and calcium ion were required to enhance thermostability. ULam111 formed one intramolecular disulfide bond at Cys31-Cys34 in the loop between β₂ and β₃, which was considered to serve as a key structural feature in stabilizing the loop above the catalytic cleft of ULam111. At the same position, TmLam has the histidine and proline residues, while PfLamA adopts the isoleucine and proline residues (Fig. S1). The C31S/C34S mutant showed decreased thermostability in our detectable temperature range (especially from 15 to 30 °C). Therefore, the loop including Cys31-Cys34 played a pivotal role in regulating thermostability.

Substrate specificity of ULam111. The kinetic parameters of ULam111 on different substrates are summarized in Table 2. ULam111 are characterized by \( K_m \) values of between 0.56 and 1.60 mg ml\(^{-1}\) and catalytic efficiencies of between 2.9 and 58 ml mg\(^{-1}\) s\(^{-1}\). ULam111 showed the high activity toward laminarin A from Laminaria digitata and curdlan from Alcaligenes faecalis. Curdlan is composed only \( \beta\)-1,3-glycosidic bonds, and the content of \( \beta\)-1,3-linkage in laminarin A is higher than those in laminarin B and glucan from Eisenia bicyclis and Flammulina velutipes, respectively. In addition, \( k_{cat} \) value toward lichenin (\( \beta\)-1,3/\( \beta\)-1,4) was 10-fold lower than that toward curdlan (\( \beta\)-1,3) and laminarin A (\( \beta\)-1,3/\( \beta\)-1,6). It was reported that substrate specificity was dependent on a straight groove or bent shape suitable for binding the linear \( \beta\)-1,3-1,4-linkages of glucan and \( \beta\)-1,3-glucan, respectively ²⁴, ³¹. In ZgLamA, the unique additional loop including His170, Glu250, and Glu263 on bent groove was attributed to the binding of \( \beta\)-1,3-linkage. The absence of this loop in BglF and deletion in PfLamA both contributed to the substrate selectivity toward \( \beta\)-1,3-1,4-linkages of glucan ¹⁶, ²³. However, ULam111 showed a predominant specificity toward the helical conformation of the \( \beta\)-1,3-linkages of laminarin (Fig. 6 and Table 2) with a straight groove at its distinctive mode compared with ZgLamA, BglF and PfLamA. A structural superposition of ULam111 with ZgLamA revealed that ULam111 displayed no additional loop to bind laminarin (Fig. 2). Figure 3 showed that ULam111 bound both substrates with a similar \( \beta\)-1,3-linkage mode at subsites −1 and −2. However, the glucosyl moiety was bound to the catalytic cleft in a completely different mode at subsite −3. Some unique residues in ULam111, such as Asn33 and Trp113, could form hydrogen bonds that prefer to degrade \( \beta\)-1,3-linked laminarin. On the other hand, the different \( K_m \) values were observed between lichenin (\( \beta\)-1,3/\( \beta\)-1,4) and glucan (\( \beta\)-1,3/\( \beta\)-1,6) (Table 2), which showed that the \( \beta\)-1,6-linkage of substrate has a greater influence on \( K_m \) than the \( \beta\)-1,4-linkage. These results suggest that the \( \beta\)-1,6-linkage may have an inhibitory effect.
against the binding of $\beta$-1,3-linkage at the active site because 1,6-linked glucosyl residues on laminarin/glucan constitute branch points on the all-1,3-linked backbone. Therefore, ULam111 showed the high affinity toward $\beta$-1,3-linked substrates. However, lichenin is a strictly linear polysaccharide composed of a 1,4-linkage backbone which also contains 1,3-linked “kinks” randomly throughout the chain. It may explain the phenomenon that ULam111 showed low activity toward $\beta$-1,4-linked lichenin.

**Table 2.** Kinetic Parameters of ULam111 Wild Type and F212W on Several Substrates. All assays were repeated three times, and the data are shown as mean ± S.D.

Table: | Enzymes | Substrates | Glycosidic bond(s) | $K_m$ (mg ml$^{-1}$) | $V_{max}$ (U mg$^{-1}$) | $k_{cat}$ (s$^{-1}$) | $k_{cat}/K_m$ (ml mg$^{-1}$ s$^{-1}$) |
|---------|------------|-------------------|---------------------|--------------------------|-----------------|-----------------------------|

highest among those toward all tested substrates. F212W mutant reduced the degrading activity toward laminarin to glucose within the initial 30 min (Fig. S4), which implied that phenylalanine has less steric hindrance than tryptophan and was the optimal residue for substrate recognition.

Materials and Methods

Cloning, expression, and purification. A gene encoding the candidate β-1,3-glucanase, termed ULam111 (GenBank accession no. LC202090), was found in the draft genome sequence of the Flavobacterium sp. strain UMI-01 as previously analyzed27. Genomic DNA was prepared from strain UMI-01 as previously described27 and used as a template for genomic polymerase chain reaction (PCR) with the Q5 High-Fidelity DNA Polymerase DNA polymerase (New England Biolabs, Ipswich, MA) and a pair of specific primers, F1 (5′-GTTCGGCTAAAAACACTGAAGCTG-3′) and F2 (5′-ATCAATGCAATCTAAATTCCGTG-3′), for the 5′- and 3′-untranslated regions, respectively. PCR was conducted using temperature settings of 95 °C for 5 min followed by 30 cycles of 95 °C for 15 s, 55 °C for 15 s, and 72 °C for 45 s. The final step for extension was 72 °C for 2 min. Amplified DNA was subcloned into the pTac-1 vector (BioDynamics, Tokyo, Japan) and sequenced with a genetic analyzer 3130xl (Applied Biosystems, Foster City, CA). DNA encoding residues 18–251 were amplified with a primer set of F2 (5′-AGGTAATACACGTACTAAGGAAAAAAGCCTG-3′) and R2 (5′-CACCCTCCACGGATCCTGGTACCATATAGTC-3′), and PCR was conducted as described above.

The ULam111 gene was cloned into a modified pCold I vector (Takara Bio, Shiga, Japan) as previously described27 between the Nco I and Bam HI sites using an In-fusion HD cloning kit (Clontech, Mountain View, CA). The expressed ULam111 protein was fused to a modified octahistidine (His8) tag (HHHHHHHH) at the C-terminus connected by a linker of GSGGGGGGG. The plasmid vector was transformed into Rosetta gami 2(DE3) (Merck Millipore, Billerica, MA) for protein expression.

Escherichia coli Rosetta gami 2(DE3) (Merck Millipore, Billerica, MA) for protein expression.

To obtain the selenomethionine-labeled ULam111 (ULam111SeMet), cells were transferred into M9 medium supplemented with 50 mg ml−1 selenomethionine (SeMet), when the OD600 reached 0.513, 14. The expression and purification of ULam111SeMet were the same as the native protein described above.

Structural determination. The initial phase of ULam111SeMet was obtained using single anomalous dispersion (SAD)16. After selenium atom search and phase calculations with PHENIX AutoSol Wizard in the PHENIX program suite29, model building was automatically carried out with PHENIX AutoBuild Wizard32. Manual rebuilding and refinement of ULam111SeMet were performed with COOT14 and PHENIX.REFINE15. The structure of native ULam111 was determined by the molecular replacement method using the MOLREP program19, 20 with the ULam111SeMet structure as the initial model. Manual rebuilding and refinement of native ULam111 was performed with COOT14 and PHENIX.REFINE15, respectively. The geometry of the final structure was evaluated with the program Rampage41. The coordinates of ULam111 have been deposited into the Protein Data Bank (PDB) with the accession number (5WUT).

Structural analysis. Structural analysis was carried out using a set of programs: Dali39 was used for the search of similar structures from the database32, DalLite42 was used for the superposition of molecules, ESPript42 was used for the preparation of alignment figures, and PymOL (http://pymol.sourceforge.net/) for the depiction of structures.

We failed to obtain cocrystals of ULam111 and laminarin. Two types of tetrasaccharides (β-1,3-linkages and β-1,3-1,4-linkages, respectively) were modeled on the ULA111 structure based on the superposition of β-1,3-glucanase ZgLamA from Zobellia galactanivorans (PDB code: 4BOW; sequence identity, 34%; preferable
β-1,3-linkages) and β-1,3,1,4-glucanase H(A16-M) (PDB code: 1U0A; sequence identity, 17%; preferable β-1,3,1,4-linkages). Glucolonolactone was modeled on the superposition of TmLam from Thermotoga maritima (PDB code: 3AZX).

Activity assay. Measurements of Ulam111 activity were performed using the ferricyanide reducing sugar assay. The reaction conditions were as follows: 0.3% (w/v) laminarin, 10 mM NaPi (pH 6.0), 100 mM NaCl, 0.1 mg ml−1 BSA, and 0.1 μg ml−1 Ulam111 at 30°C. One unit (1U) was defined as the amount of enzyme required to liberate 1 μmol of reducing sugar per minute. Data are presented as the mean ± S.D. from three independent experiments. The substrate specificity was assessed according to the oligosaccharide degradation of laminarin A (β-1,3,1,6-linkages) from Laminaria digitata (Sigma-Aldrich, St. Louis, MO), laminarin B (β-1,3,1,6-linkages) from Eiseia bicylis (Tokyo Chemical Industry, Tokyo, Japan), glucan (β-1,3,1,6-linkages) from Flammulina velutipes, curdlan (β-1,3-linkages) from Alcaligenes faecalis (Wako Pure Chemical Industries, Osaka, Japan), and lichenin (β-1,3,1,4-linkages) from Certraria islandica using thin-layer chromatography (TLC) with a TLC-60 plate (Merck, Darmstadt, Germany). The reaction proceeded at 30°C for 24 h and the reaction mixture was composed of 0.5% (w/v) substrates, 10 mM NaPi (pH 6.0), 100 mM NaCl, 0.1 mg ml−1 BSA, and 0.02 mg ml−1 Ulam111. Samples were developed with a solvent mixture consisting of ethyl acetate, acetic acid, and water [2:2:1 (v:v:v)] and visualized by spraying 10% (v/v) sulfuric acid in ethanol followed by heating at 130°C for 10 min. The thermostability of Ulam111 was assessed by measuring the activity after heat treatment at 15–60°C for 15 min in the reaction mixture; 1.0 mM EDTA or CaCl2 was added prior to thermostability measurements.

Kinetic studies of Ulam111 wild-type or F212W were performed in a solution containing 10 mM NaPi (pH 6.0), 100 mM NaCl, 0.1 mg ml−1 BSA, 1.0 mM CaCl2, 1 μg ml−1 wild-type or F212W enzymes, and various concentrations of substrates at 30°C. Kinetic parameters, K_m, V_max, and K_cat were calculated using the Michaelis-Menten equation with GraphPad Prism 7.0 (GraphPad software, La Jolla, CA) by employing nonlinear regression.

Data availability. Protein Data Bank (PDB): Coordinates and structure factors for the wild-type Ulam111 have been deposited in the RCSB Protein Data Bank under the accession codes 5WUT.

Acknowledgements

This work was supported by the Tohoku Marine Science Project of the Ministry of Education, Culture, Sports, Science, and Technology (MEXT), Japan; the National Natural Science Foundation of China (31771911); the Natural Science Foundation of Tianjin (16JCQNJC09200); the Overseas High-level Talents Program of Tianjin University of Science and Technology; We would like to thank the scientists and staff at the Photon Factory. The synchrotron radiation experiments were conducted at the BL-5A beamline of the Photon Factory, Tsukuba, Japan (Proposal No. 2013G652).

Author Contributions

M.T. and T.O. designed the research; H.-M.Q., T.M., A.I. and R.N. performed the experiments; H.-M.Q., T.M., A.I. and A.N. analyzed data; and H.-M.Q., T.M., A.I., T.O., and M.T. wrote the paper. All authors have approved the final version of the manuscript.
