Abstract – We study the effect of a single driven tracer particle in a bath of other particles performing the random average process on an infinite line using a stochastic hydrodynamics approach. We consider arbitrary fixed as well as random initial conditions and compute the two-point correlations. For quenched uniform and annealed steady-state initial conditions we show that in the large time \( T \) limit the fluctuations and the correlations of the positions of the particles grow subdiffusively as \( \sqrt{T} \) and have well-defined scaling forms under proper rescaling of the labels. We compute the corresponding scaling functions exactly for these specific initial configurations and verify them numerically. We also consider a non-translationally invariant initial condition with linearly increasing gaps where we show that the fluctuations and correlations grow superdiffusively as \( T^{3/2} \) at large times.

The motion of non-overtaking particles in narrow channels is known as single-file diffusion. In such one-dimensional geometry the motion of any tagged particle (TP) is hemmed by its neighbors. The study of TP motion was started independently by Harris and Jepsen [1,2] in 1965. Since then there have been numerous theoretical \[3–19\] as well as experimental studies \[20–26\]. One interesting feature is that the variance of the TP grows subdiffusively (\( \sim \sqrt{T} \)) even when individual particles are diffusive and the prefactor of \( \sqrt{T} \) depends on the initial condition (IC) \[1,3–10,13–19\]. Due to recent developments of experimental techniques like active microrheology and microfluidics \[27,28\] there has been a resurgence of interest in studying locally driven interacting particle systems. In this paper we consider the case where the TP is driven externally and study its effect on the surrounding unbiased bath particles.

Single driven TPs (DTPs) in quiescent media have been used to probe rheological properties of complex media such as polymers \[29,30\], granular media \[31,32\] or colloidal crystals \[33\], and also to study directed cellular motion in crowded channels \[34\] or the active transport of vesicles in a crowded axon \[35\]. Some practical examples of DTPs are a charged impurity being driven by an applied electric field or a colloidal particle being pulled by an optical tweezer in the presence of other colloidal particles performing random motion.

On the theoretical side, situations have been considered where the surrounding medium is a symmetric simple exclusion process. In this context the effect of the DTP has been quantified in terms of both the tracer motion and the perturbation of the density profile \[36–40\] in the steady state (SS). In particular it has been shown by using a decoupling approximation that both the mean \[36,37,39\] and the variance \[37\] of the position of the DTP grow as \( \sqrt{T} \). The full distribution of the displacement of the DTP has recently been computed in the high density limit of bath particles \[16\]. However, all these studies always rely on some approximation, and mostly considered quantities related to the displacement of the TP.

Here we consider the motion of a DTP moving inside a pool of other particles performing the random average process (RAP) in one dimension. Using a stochastic hydrodynamic description for this model with a DTP, we compute the mean and the fluctuation of the position of not only the DTP but of all the particles in the large time limit exactly. In addition, we also compute the exact large time behavior of the correlation function between the positions of any two particles.

The RAP was introduced in \[41\]. It appears in many problems like force propagation in granular media \[42,43\], in the porous medium equation \[44\], in models of mass transport \[42,44\], voting systems \[46\] or wealth distribution \[47\] and in the generalised Hammersley process \[48\].
Fig. 1: (Color online) Schematic diagram of the RAP with a driven tracer particle (0th particle colored in red) on an infinite line. $x_i$ represents the position of the $i$-th particle and $q_i = x_{i+1} - x_i$ represents the gap between the $(i+1)$-th and $i$-th particles. The driven tracer particle hops to the left with rate $p$ and to the right with rate $q$, whereas all other particles ($i \neq 0$) hop to the left or to the right with same rate $1/2$.

**RAP model:** We consider an infinite number of particles labeled by integers $k \in \mathbb{R}$ on the infinite line (see fig. 1). We denote the position of the particle $k$ at time $t$ by $x_k(t) \forall k \in \mathbb{Z}$. Each particle is allowed to move to the right or left by a random fraction $\eta \in [0,1)$ of the space available until the nearest particle in the direction of hopping. The fraction $\eta$ is drawn from some distribution $R(\eta)$ with moments $\mu_k = \int_0^1 d\eta \, \eta^k \, R(\eta)$. All particles hop to the right and left with rate $1/2$ except for the 0th particle which moves asymmetrically, to the right with rate $p$ and to the left with rate $q$. Without loss of generality we assume $p > q$.

The ICs of the particles, more precisely the initial separations $\omega_{in}$ between successive particles are chosen from some arbitrary distribution $P_{in} \propto e^{-G[\omega_{in}]}$. We are mainly interested in the following three ICs:

- **Quenched uniform (QU) initial conditions:** At initial time the particles are at fixed positions (“quenched”) with a constant spacing (“uniform”). We therefore consider $x_k(0) = k\nu_0$, where $\nu_0^{-1}$ is the particle density in the RAP.

- **Quenched linear (QL) initial conditions:** For this case, the particles are arranged in such a way that the gaps between successive particles $g_k = x_{k+1} - x_k = \alpha \text{sgn}(k) (k + 1/2) + \delta_{k,0}$ grow linearly with indices $k = \pm 1, \pm 2, \ldots$ on both sides of the DTP ($k = 0$).

- **Steady-state (SS) initial conditions:** In the steady-state initial condition, a configuration is chosen randomly from the steady-state distribution obtained in the absence of DTP. This distribution is explicitly given in terms of the initial gap profile $\omega_{in}(z)$ by $	ext{Prob.}[\omega_{in}] \propto \exp(-G_{ss}[\omega_{in}])$,

$$G_{ss}[\omega] = \int_{-\infty}^{\infty} dz \left[ f(\omega) - f(\nu_0) - f'(\nu_0)(\omega - \nu_0) \right]$$

with $f(\omega) = (1 - \mu_1/\mu_2) \ln(\omega)$, $f'(\omega) = df/d\omega$. This expression of $G_{ss}[\omega]$ can be obtained by following the procedure detailed in [49,50], which mainly consists in deriving an appropriate hydrodynamic description starting from a microscopic point of view.

The SS IC is the one expected to be realized in most experiments [29,31–33], as the tracer particle is usually held and the rest of the fluid is left untouched. Taking measurements for the QU IC would require holding all the particles initially at fixed positions using either optical/magnetic tweezers or a periodic field, and then turning them off before starting the noisy dynamics. We here mainly focus on the difference between QU and SS ICs. The QL IC case is briefly discussed to demonstrate the possibility of superdiffusive behaviour.

**Results:** In the large time limit, we compute the mean, variance and correlations of the particles for arbitrary ICs. In particular, we show that for both QU and SS ICs, the mean $y_k(T) = \langle x_k(t) \rangle$ and the two-point correlation $c_{kl}(T) = \langle x_k(T)x_l(T) \rangle - \langle x_k(T) \rangle \langle x_l(T) \rangle$ have the following scaling forms:

$$y_k(T) = \nu_0 \sqrt{2\mu_1 T} \, Y_b(k/\sqrt{2\mu_1 T}),$$

$$c_{kl}(T) = \nu_0^2 \sqrt{2\mu_1 T} \, C_{bl}(k/\sqrt{2\mu_1 T}, l/\sqrt{2\mu_1 T}),$$

where $b = \frac{p-q}{p+q}$ is the bias and $\langle \ldots \rangle$ denotes the average over stochastic evolution as well as over ICs. These scaling behaviors (2) have recently been observed in numerics and $Y_b(x)$ has been obtained in [51] using a microscopic point of view. Here we rederive it using a hydrodynamic approach and show that it is given by

$$Y_b(u) = u + b \left[ c^{-u^2}/\sqrt{\pi} - |u|\text{Erfc}(|u|) \right]$$

for both QU and SS ICs.

For the zero-drive case ($b = 0$) the scaling function $C_{0}(u, v)$ has been computed in [52] for both ICs. In this translationally invariant case the correlation function $C_{0}(u, v)$ depends only on the separation $|u - v|$ between the two particles. On the other hand, in the presence of DTP the system is not translationally invariant and the correlation functions depend on the scaling variables $u$ and $v$ individually.

For the driven case an attempt to compute the scaling function $C_{b}(u, v)$ for the QU IC has been made but for small drive strength $|p - q|$ and for the totally asymmetric choice $q = 0$ (or $b = 1$) [51]. In the latter case $C_{1}(u, v)$ has been computed only for $u \geq 0$ and $v \geq 0$ [51]. Here we compute these scaling functions over the full 2D plane exactly for arbitrary $p$ and $q$ and for arbitrary ICs. In particular, we show that the variance of the position of the DT process is given by

$$c_{0,0}(T) = \nu_0^2 \sqrt{2\mu_1 T} \, \frac{\mu_2\sqrt{(\sqrt{2} - 1)^2}}{\sqrt{\pi}(\mu_1 - \mu_2)} A(b),$$

where $A$ is given by

$$A(b) = \begin{cases} 
(\sqrt{2} + 1)(1 - b^2) + \frac{1}{2} (1 + b^2), \quad \text{QU}, \\
(\sqrt{2} + 1)(1 - b^2) + \frac{2 + \sqrt{2}}{2} (1 + b^2), \quad \text{SS}.
\end{cases}$$

Equations (4), (5) match with previously known results for $b = 0$ for both ICs [52], and $b = 1$ in the QU case [51]. Note that the ratio of the prefactors in the QU and SS ICs depends on the drive and becomes $\sqrt{2}$ for $b = 0$, as observed earlier [13,18,52,53].

54003-p2
To prove the above results, we map the RAP to a mass transfer problem [51]. The mass at site $k$ is equal to the the gap $g_k(t) = x_{k+1}(t) - x_k(t)$ between the positions of the $(k + 1)$-th and $k$-th particles in RAP for all $k$. The DTP is mapped to a special link (−1, 0) where the mass transfer occurs with rate $p$ to the left and $q$ to the right, while all other links are symmetric. In terms of the gaps, the displacement of the $k$-th particle at time $T$ is given by $x_k(T) = \sum_{k=-\infty}^{k=\infty} [g_k(T) - g_0(0)]$.

In the large length and time scales it seems convenient to consider a continuum description of the system. For that we coarse-grain the gap label $k$ to get a continuous variable $z$ as done in [10]. This allows us to describe the system in terms of the conserved mass density field $\omega(z, t)$ and the current field $j(z, t)$, which are related via the continuity equation $\partial_t \omega(z, t) = -\partial_z j(z, t)$. The displacement of the $k$-th particle can be expressed as

$$X_k(T) = x_k(T) - x_k(0) = \int_{-\infty}^{\infty} dz \ [\omega(z, t) - \omega(z, 0)]. \tag{6}$$

Since the TP is driven, the region at its front will be more crowded than the region at its back, thus creating a lower gap density in front of it than at its back. This leads to the following discontinuity [51]:

$$q \omega(z, t)_{|z=0^-} = p \omega(z, t)_{|z=0^+}. \tag{7}$$

Since the mass transfer model falls into the class of “gradient type” models, the typical (and also the average) gap density profile $\bar{\omega}(z, t)$ satisfies the diffusion equation [54,55]

$$\partial_t \bar{\omega} = \partial_z [D(\bar{\omega}) \partial_z \bar{\omega}], \tag{8}$$

where $D(\omega) = \mu_1/2$ is the diffusivity [45]. To solve (8) we introduce the Green’s function $F_k(z, z', t)$ that satisfies $\partial_t F_k = \frac{\mu_1}{2} \partial_z^2 F_k$ with the discontinuities $\{1 - b\} F_k|_{z=0^-} = (1 + b) F_k|_{z=0^+}$ and $(F_k)^{0^+}_{0^-} = 0$ and the delta initial condition $F_k(z, z', 0) = \delta(z - z')$. The Green’s function can be determined by standard methods and is given by

$$F_k(z, z', t) = \frac{e^{-\frac{(z-z')^2}{2\sqrt{\pi} \mu_1 t}} - b \sgn(z) e^{-\frac{(z-z')^2}{2\sqrt{\pi} \mu_1 t}}}{\sqrt{2\pi} \mu_1 t}. \tag{9}$$

One can solve for $\bar{\omega}(z, t)$ satisfying (7) for arbitrary fixed IC $\omega_{in}(z')$ to get

$$\bar{\omega}(z, t) = \int_{-\infty}^{\infty} F_k(z, z', t) \omega_{in}(z') \, dz', \tag{10}$$

where $\sgn(z)$ is the sign function. Using $(\omega_{in}(z'))_{\rho_{in}} = \nu_0$ both for QU and SS ICs, in the above equation we explicitly get $\bar{\omega}(z, T) = \Omega_b(z/\sqrt{2\mu_1 T})$ with $\Omega_b(0) = \nu_0 [1 - b \sgn(u) \text{erfc}[u]]$. Inserting this result in (6) we obtain (2), (3).

For the QL IC case, where the particles are initially placed at positions $x_k(0) = (\alpha/2) \sgn(k) k^2$, $\forall k \in \mathbb{Z}$ one has $\omega_{in}(z') = \alpha z'^2$. Using this in (10) and performing the integral one gets $\bar{\omega}(z, T) = \sqrt{2\mu_1 T} \Omega_{bQ}(z/\sqrt{2\mu_1 T})$, where $\Omega_{bQ}(u) = |u| [1 - b \sgn(u)][e^{-u^2}/\sqrt{\pi}] - |u| \text{erfc}[u)]$.

Once again inserting this result in (6) one obtains $y_k(T) \sim T$ in contrast to $\sim \sqrt{T}$ behaviour: $y_k(T) = 2\mu_1 T \alpha \delta_k(k/\sqrt{2\mu_1 T})$ where $\delta_k(u) = \sgn(u) u^2 + \Theta(u)/2 + |b - \sgn(u)][1 + 2u^2 \text{erfc}[u]] - 2u e^{-u^2}/\sqrt{\pi}/4$ and $\Theta(x)$ is the Heaviside theta function.

We now focus on computing the variances and the two point correlations. For that we need to consider the fluctuations of the density and current fields about their mean behaviors. According to the macroscopic fluctuation theory [18,50], the fluctuations in these two fields can be described by adding Gaussian fluctuations to the current: $j(z, t) = - (\mu_1/2) \partial_z \omega(z, t) + \sigma(\omega(z, t)) n(z, t)$ where $\sigma(\omega)$ is the mobility and $n(z, t)$ is a Gaussian white noise satisfying $\langle n(z, t) \rangle = 0$ and $\langle n(z, t) n(z', t') \rangle = \delta(z - z') \delta(t - t')$. For the mass transfer model one can show $\sigma(\omega) = \sqrt{\var_1 \var_2}$ [45]. Due to the Gaussian nature of the noise, the joint probability of observing density and current profiles $\omega(z, t)$ and $j(z, t)$ different from the typical profiles is also Gaussian and is given by [18,50]

$$\mathbb{P}[\omega, j] \approx \exp \left[ - \int_0^T \int_{-\infty}^{\infty} dz \frac{[j + (\mu_1/2) \partial_z \omega(z, t)]^2}{2\sigma(\omega(z, t))^2} \right], \tag{11}$$

where $\langle \omega, j \rangle$ satisfy the continuity equation. Here the symbol $\rangle$ represents logarithm equivalence.

In order to compute $c_{k,T}(T)$ we look at the joint distribution of the displacements $X_k(t)$ and $X_l(t)$. This distribution is completely characterized by the generating function

$$\mu(\lambda_k, \lambda_l) = \langle \exp[\lambda_k X_k(T) + \lambda_l X_l(T)] \rangle, \tag{12}$$

where $\lambda_k, \lambda_l$ are Lagrange multipliers. From this quantity the two-particle connected correlations can be obtained as $c_{k,l}(T) = \langle [\delta k \ln(\mu(\lambda_k, \lambda_l))/\partial \lambda_k \partial \lambda_l]_{\lambda_k = 0, \lambda_l = 0} \rangle$.

To proceed further we follow the technique developed by Kravitsky et al. [18] and compute $\mu(\lambda_k, \lambda_l)$ using the joint distribution (11). We consider an ensemble of ICs $\omega_{in}$ drawn with probability $\mathbb{P}_{\omega} \propto e^{-G[\omega_{in}]}$. From (11) and (12) we see that $\mu(\lambda_k, \lambda_l)$ can be expressed as a path integral

$$\mu(\lambda_k, \lambda_l) = \int D[\omega_{in}] e^{-G[\omega_{in}]} \mathbb{P}_{\omega} \int D[\omega, h] e^{-S[\omega, h]}, \tag{13}$$

where $h$ is an auxiliary field. We here stress the fact that the integrals over $\omega$ and $h$ have to be evaluated for a fixed IC $\omega_{in}$ before taking the average over initial configurations. The action $S$ is obtained via Martin-Siggia-Rose formalism [18],

$$S[\omega, h] = -\lambda_k X_k(T) - \lambda_l X_l(T) + \int_0^T \int_{-\infty}^{\infty} dz \left[ h \partial_t \omega + (\mu_1/2) \partial_z \omega (\partial_z h) - \langle \sigma(\omega)/2 \rangle (\partial_z h)^2 \right], \tag{14}$$

where we note that the integrand is singular at $z = 0$ at all times. At large times $T$ the path integral over $\omega$
and $H$ can be computed by the saddle-point method to give $\sim e^{-S[\omega]}h^{-[\omega]}$, as it is dominated by optimal paths $(\omega^*(z,t), h^*(z,t))$ that depend on the initial configuration $\omega_{in}$. In the final step one has to perform the remaining path integral over $\omega_{in}$ in (13) in the annealed case. This can again be carried out by the saddle-point method.

We now have to find the optimal paths $(\omega^*(z,t), h^*(z,t))$ for arbitrary fixed IC $\omega_{in}(z)$. Using variational calculus we obtain that the optimal paths satisfy the following coupled differential equations (see footnote 1):

\[
\partial_t \omega^*(z,t) = (\mu_1/2)\partial_z^2 \omega^* - \partial_z (\sigma(\omega^*) \partial_z h^*),
\]

\[
\partial_t h^*(z,t) = -(\mu_1/2)\partial_z^2 h^* - (\sigma(\omega^*)/2) (\partial_z h^*)^2,
\]

where $\sigma(\omega) = d\sigma/d\omega$. Writing $A(z)_{0+}^0 = A(0^-) - A(0^+)$ for short, one can show that the solutions of (15) and (16) have to satisfy the discontinuity conditions

\[
q \omega^*(z,t)|_{z\rightarrow0^-} = p \omega^*(z,t)|_{z\rightarrow0^+}, \quad h^*(z,t)|_{0^+} = 0,
\]

\[
\frac{\mu_1}{2} \partial_z \omega^*_0 = 0, \quad [\partial_t \omega^*_0]|_{0^+} = 0
\]

and the initial/boundary conditions

\[
\omega^*(z,0) = \omega_{in}(z), \quad h^*(z,T) = \lambda_k \Theta(k-z) + \lambda_l \Theta(l-z),
\]

\[
\omega^*(z,T) = \lambda_k \Theta(k-z) + \lambda_l \Theta(l-z).
\]

The solution is given by $\omega^*(z,t) = \omega_{in}(z)$. The action in (14) depends on the integrals like $\Phi_\epsilon(z,T) = \int_{-\infty}^\infty \omega(z,t)dt$. Using $\omega^*(z,t) = \partial_z h^*(z,t)$ and performing some manipulations, we obtain

\[
\Phi_\epsilon(z,t) = \int_0^t dt \int_{-\infty}^\infty dz' \sigma(\omega(z')) \partial_z h_\epsilon(z',t) \partial_\epsilon h_\epsilon(z',t).
\]

We can now insert $h_\epsilon$ and $\Phi_\epsilon$ functions in (14) and simplify using eqs. (21), (22) and find

\[
S[\omega^*, h^*] = -\frac{1}{2} \int_0^T dt \int_{-\infty}^\infty dz \sigma(\omega) \left( \lambda_k f_{\epsilon k}^0 + \lambda_l f_{\epsilon l}^0 \right)^2
\]

\[
-\lambda_k \int_{-\infty}^{\infty} dz (\Sigma - \omega_{in}) - \lambda_l \int_{-\infty}^{\infty} dz (\Sigma - \omega_{in}) + O(\lambda^2),
\]

where $\Sigma(z,t)$ and $f_{\epsilon k}^0(z,t) = F_\epsilon(-\epsilon, z, T-t)$ are given by (9) and (10). Once we have the optimal value of the action $S$ for given IC $\omega_{in}$, we have to perform the average over the initial configurations by evaluating the remaining path integral over $\omega_{in}$ in (13).

To include all the ICs SS, QU and QL in a single analysis, we consider a general Gaussian distribution of $\omega_{in}$, $G[\omega_{in}] \sim \int dz (\omega_{in}(z) - \chi(z))^2$. The SS, QU and QL ICs are obtained by taking $(\chi, \Sigma) \equiv (\nu_0, \mu_1^2, \mu_2^2)$, $(\nu_0, 0)$ and $(\alpha |z|, 0)$, respectively. In the supplementary material in footnote 1 we show that

\[
\epsilon_k, l |\chi, \Sigma) = \int_0^T dt \int_{-\infty}^\infty dz \sigma(\omega(z)) \left( f_{\epsilon k}^0(z,t) f_{\epsilon l}^0(z,t)
\]

\[
+ \int_{-\infty}^\infty dz \Sigma(z)^2 F_{\epsilon k}^0(z,T) F_{\epsilon l}^0(z,T),
\]

obtained from (18). The discontinuities are obtained from (17) as

\[
(1 + b)\omega_0^+(0^+, t) = (1 - b) \omega_0^-(0^-, t),
\]

\[
\mu_1 \partial_z \omega_0^+(0^+, t) = \partial_z h_0^+(0^+, t),
\]

\[
\mu_1 \partial_z h_0^+(0^+, t) = 0.
\]

where $b = \frac{\gamma - \gamma}{\gamma + \gamma}$. We first solve (22) with conditions (24) and (26). Using a similar procedure as for the density profile, one can show that the solutions are given by

\[
h_\epsilon(z,t) = \frac{1}{2} \frac{\sqrt{z - \epsilon}}{\sqrt{2\mu_1(T-t)}} + \frac{b}{2} \frac{\sqrt{|z| + |\epsilon|}}{\sqrt{2\mu_1(T-t)}}.
\]

Now that we have $h_\epsilon(z,t)$ explicitly, we can solve (21). The solution is given by

\[
\omega_\epsilon(z,t) = -\int_0^t dt \int_{-\infty}^\infty dz' F_\epsilon(z', t - \tau) \partial_\epsilon h_\epsilon(z', \tau),
\]

\[
F_\epsilon(z', t) \text{ is given in (9). The action in (14) depends on the integrals like } \Phi_\epsilon(z,t) = \int_{-\infty}^\infty \omega_\epsilon(z,t) dt.
\]

\[
\Phi_\epsilon(z,t) = \int_0^t dt \int_{-\infty}^\infty dz' \sigma(\omega(z')) \partial_z h_\epsilon(z', \tau) \partial_\epsilon h_\epsilon(z', \tau).
\]

\[
\Phi_\epsilon(z,t) = \int_0^t dt \int_{-\infty}^\infty dz' \sigma(\omega(z')) \partial_z h_\epsilon(z', \tau) \partial_\epsilon h_\epsilon(z', \tau).
\]
from (10). The first term comes from the time evolution and inserting the corresponding \( \chi \) evaluated numerically for arbitrary initial conditions after adding the corresponding \( \Sigma \) as can be seen from (10). The first term comes from the time evolution only, while the second term, proportional to \( \Sigma^2 \), comes from the variance of the initial configuration. In particular this expression shows that the variance \( c_{k,k} [\chi,0] < c_{k,k} [\chi, \Sigma] \) for any choice of \( \chi \) and \( \Sigma \) and for any particle \( k \).

In general the integrals appearing in (31) can easily be evaluated numerically for arbitrary initial conditions after inserting the corresponding \( \chi \) and \( \Sigma^2 \). In some special cases further analytical simplifications are possible. For the QU and SS ICs the integrals in \( c_{0,0} \) can be performed analytically and one can obtain the variance of the DTP as given in (4) and (5). In fig. 2 we compare these predictions with numerical simulations and find good agreement. Similarly, for these two ICs in the totally asymmetric case \( b = 1 \), one finds the following expressions of the scaling functions defined in (2) after inserting \( (\chi, \Sigma^2) \) \( \equiv (\nu_0, \mu_0^2 \mu_1^{-1} - \mu_2^{-1}) \) and \( (\nu_0,0) \) in (31) for SS and QU ICs, respectively, and simplifying. Writing \( a = \frac{\mu_2}{2\pi(\mu_1 - \mu_2)} \) for short, we get

\[
C_1^{QU}(u,v) = a \int_0^1 \frac{d\tau}{\tau} \left( \frac{1}{\sqrt{1 + \tau}} \right)^2 \times \int_{-\infty}^{\infty} dy \left[ 1 - \text{erfc} \left( \frac{y}{\sqrt{1 - \tau}} \right) \right] \times \left[ e^{-\frac{(y-u)^2}{\tau}} + \text{sgn}(y) e^{-\frac{(y+v)^2}{\tau}} \right] \times \left[ e^{-\frac{(y-v)^2}{2\mu_1}} + \text{sgn}(y) e^{-\frac{(y-v)^2}{2\mu_2}} \right],
\]

(32)

\[
C_1^{SS}(u,v) = C_1^{QU}(u,v) + \frac{\pi a}{2} \int_{-\infty}^{\infty} dy \left[ \text{erfc} \left( |y-u| + |y+v| \right) + \text{erfc} \left( |u| + |v| \right) \right] \times \left[ \text{erfc} \left( |y-v| + |y+v| \right) + \text{erfc} \left( |u| + |v| \right) \right].
\]

(33)

For the \( b = 1 \) case we compare numerical results for \( C_1(u,v) \) and \( C_1(0,u) \) with the theory (32) and (33) in figs. 3 and 4 for both ICs. As expected, these expressions are coherent with the results found in [52] and [51] in the appropriate cases.

In fig. 3 we find that the variances of the positions of particles in the front of the DTP are smaller than at the back, because the particles in the front have less space than those at the back. This intuitively suggests that the variance should be maximum just behind the DTP. On the contrary, in fig. 3 we see that the maximum occurs at a finite distance \( O(\sqrt{T}) \) behind the DTP. It seems like the driven motion of the TP creates a density perturbation moving forward which is accompanied by a corresponding vacancy perturbation moving backwards similar to what happens in exclusion processes [10].

Figure 4 displays the plot of the correlation (at time \( T \)) between the DTP and the \( i \)-th particle as a function of the scaling variable \( u = 1/\sqrt{2\mu_1 T} \). We notice that it has a vanishing slope for \( u \to 0^+ \) in the QU IC case implying that the particles at the front of the DTP are equally correlated up to a distance \( O(\sqrt{T}) \). This is another artifact of the crowding phenomenon at \( u > 0 \). On the other hand, for SS ICs there is an extra contribution from the initial correlations that dominates at large times.

It is worth noting that the \( \sqrt{T} \) growth of the correlation holds only for the translationally invariant ICs like QU.
and SS. This however does not hold for non-translationally invariant ICs like the QL IC for which one has $\chi(z) = a |z|$ and $\Sigma = 0$. In this case the DTP gets enough space on both sides and, as a result, the correlation grows superdiffusively $c_{k,l}(T) = T^{3/2} a$ $c_k^{QL}(k/\sqrt{2}\mu_1 T, l/\sqrt{2}\mu_1 T)$ at large times (see footnote 1 for the proof).

In this work we consider a single-file system, the RAP, in the presence of a locally driven particle which drives the whole system out of equilibrium. The drive manifests itself into discontinuities of the hydrodynamic fields at the DTP position. For this model we obtain the large-time two-particle correlation function for any IC exactly. The two-point correlation functions grow as $\sqrt{T}$ for both the QU and SS ICs, similar to the annealed/quenched dichotomy in non-driven systems. This is in contrast with exclusion processes, where nonlinearities play an important role in the quenched case [56]. We also have looked at another specially designed quenched linear initial condition where the two-point correlation functions grow as $T^{3/2}$ and have scaling forms under rescaling of particle labels by $T^{1/2}$. These correlation functions will serve as a benchmark in analyzing the trajectories of a driven tracer particle in traffic flow, in active microrheology [27] and microfluidics [28] experiments. An extension of the method used here to a larger class of single-file systems would be of great interest.
