Cosmic necklaces are hybrid topological defects consisting of monopoles and strings, with two strings attached to each monopole. We argue that the cosmological evolution of necklaces may significantly differ from that of cosmic strings. The typical velocity of necklaces can be much smaller than the speed of light, and the characteristic scale of the network much smaller than the horizon. We estimate the flux of high-energy protons produced by monopole annihilation in the decaying closed loops. For some reasonable values of the parameters it is comparable to the observed flux of ultrahigh-energy cosmic rays.

The observation of cosmic ray particles with energies higher than $10^{11} \, GeV$ gives a serious challenge to the known mechanisms of acceleration. The shock acceleration in different astrophysical objects typically gives maximal energy of accelerated protons less than $(1 - 3) \cdot 10^{10} \, GeV$. The unipolar induction can provide the maximal energy $1 \cdot 10^{11} \, GeV$ only for the extreme values of the parameters. Much attention has recently been given to acceleration by ultrarelativistic shocks. The particles here can gain a tremendous increase in energy, equal to $\Gamma^2$, at a single reflection, where $\Gamma$ is the Lorentz factor of the shock. However, it is known (see e.g. the simulation for pulsar relativistic wind in [4]) that particles entering the shock region are captured there or at least have a small probability to escape.

Topological defects (for a review see [4]) can naturally produce particles of ultrahigh
energies (UHE) well in excess of those observed in cosmic rays (CR). In most cases the problem with topological defects is not the maximal energy, but the fluxes.

*Cosmic strings* can produce particles when two segments of string come into close contact, as in *cusp* events [3]. When the distance between two segments of the cusp becomes of the order of the string width, the cusp may “annihilate” turning into high energy particles. However, the resulting cosmic ray flux is far too small [9].

*Superconducting strings* [10] appear to be much better suited for particle production. Moving through cosmic magnetic fields, such strings develop electric currents and copiously produce charged heavy particles when the current reaches certain critical value. The CR flux produced by superconducting strings is affected by some model-dependent string parameters and by the history and spatial distribution of cosmic magnetic fields. Models considered so far failed to account for the observed flux [11,12].

*Monopole-antimonopole pairs* (\(M\bar{M}\)) can form bound states and eventually annihilate into UHE particles [13], [14]. For an appropriate choice of the monopole density \(n_M\), this model is consistent with observations; however, the required (low) value of \(n_M\) may be difficult to explain.

We shall consider here another potential source of UHE CR, the topological defects which have not been much studied so far: *cosmic necklaces*. Such defects can be formed in a sequence of symmetry breaking phase transitions \(G \rightarrow H \times U(1) \rightarrow H \times Z_2\). If the group \(G\) is semisimple, then the first phase transition produces monopoles, and at the second phase transition each monopole gets attached to two strings, with its magnetic flux channeled along the strings. The resulting necklaces resemble “ordinary” cosmic strings with monopoles playing the role of beads. “Realistic” particle physics models with necklaces can readily be constructed [15].

The evolution of necklaces is rather complicated, and its analysis would require high-resolution numerical simulations. Here we shall attempt only to indicate the relevant physical processes and to give very rough estimates for the efficiency of some of these processes.

The monopole mass \(m\) and the string tension \(\mu\) are determined by the corresponding
symmetry breaking scales, \( \eta_s \) and \( \eta_m \) \((\eta_m \gg \eta_s)\),

\[
m \sim \frac{4\pi \eta_m}{\epsilon}, \quad \mu \sim 2\pi \eta_s^2.
\]

Here, \( \epsilon \) is the gauge coupling. The mass per unit length of string is equal to its tension, \( \mu \). Each string attached to a monopole pulls it with a force \( F = \mu \) in the direction of the string. The monopole radius \( \delta_m \) and the string thickness \( \delta_s \) are typically of the order \( \delta_m \sim (\epsilon \eta_m)^{-1} \), \( \delta_s \sim (\epsilon \eta_s)^{-1} \).

Monopoles are formed at a temperature \( T_m \sim \eta_m \). Their initial average separation, \( d \), can range from \( \delta_m \) (for a second-order phase transition) to the horizon size (for a strongly first-order transition). The monopoles are diluted by the expansion of the universe, so that \( d \) grows as \( d \propto T^{-1} \). There is some additional decrease in the monopole density, and associated increase in \( d \), due to \( M \bar{M} \) annihilation. The latter process, however, is rather inefficient.

At the second phase transition, each monopole gets attached to two strings, resulting in the formation of necklaces. There will be infinite necklaces having the shape of random walks and a distribution of closed loops. The two strings attached to a monopole are pulling it with an equal force; hence, there is no tendency for a monopole to be captured by the nearest antimonopole, unless their separation is comparable to the string thickness, \( \delta_s \).

An important quantity for the necklace evolution is the dimensionless ratio

\[
r = \frac{m}{\mu d},
\]

The average mass per unit length of necklaces is \((r + 1)\mu\). The initial value of \( r \) can be large \((r \gg 1)\) or small \((r \ll 1)\), depending on the nature of the two phase transitions.

We expect the necklaces to evolve in a scaling regime. If \( \xi \) is the characteristic length scale of the network, equal to the typical separation of long strings and to their characteristic curvature radius, then the force per unit length of string is \( f \sim \mu/\xi \), and the acceleration is \( a \sim (r + 1)^{-1}\xi^{-1} \). We assume that \( \xi \) changes on a Hubble time scale \( \sim t \). Then the typical distance travelled by long strings in time \( t \) should be \( \sim \xi \), so that the strings have enough time to intercommute in a Hubble time. This gives \( at^2 \sim \xi \), or
\[ \xi \sim (r + 1)^{-1/2}t. \quad (3) \]

The typical string velocity is \( v \sim (r + 1)^{-1/2} \).

For \( r \ll 1 \) the monopoles are subdominant, and the string evolution is essentially the same as that of ‘ordinary’ strings without monopoles. The opposite case \( r \gg 1 \) is much different: the string motion is slow and their average separation is small. Like ordinary strings, cosmic necklaces can serve as seeds for structure formation. Significant quantitative changes in the corresponding scenario can be expected for \( r \gg 1 \).

Disregarding \( M \bar{M} \) annihilation, the evolution of \( r(t) \) can be analyzed using the energy balance equation

\[ \dot{E} = -PV - \dot{E}_g. \quad (4) \]

Here, \( E \) is the energy of long necklaces in a co-moving volume \( V \), \( P \) is the effective pressure, and \( \dot{E}_g \) is the rate of energy loss by gravitational radiation from small-scale wiggles on long strings. If the scale of the wiggles is set by the gravitational back-reaction, then the strings radiate a substantial part of their energy in a Hubble time [16,17], and we can write \( \dot{E}_g = \kappa_g N m / r t \) where \( N \) is the number of monopoles in volume \( V \) and \( \kappa_g \sim 1 \). The effect of loop formation is not relevant for the evolution of \( r(t) \) and has not been included in Eq.(4).

For \( r \ll 1 \), the effect of monopoles on the string dynamics is negligible, and we can write \( P = (Nm/3Vr)(2v^2 - 1) \), where \( v \) is the rms string velocity. Then, with a power-law expansion \( a(t) \propto t^\nu \), we obtain the following equation for \( r(t) \):

\[ \frac{\dot{r}}{r} = -\kappa_s t + \kappa_g \frac{t}{r}, \quad (5) \]

where \( \kappa_s = \nu(1 - 2v^2) \). The first term on the rhs of Eq.(5) describes the string stretching due to expansion of the Universe while the second term describes the competing effect of string shrinking due to gravitational radiation [18]. In this regime, we can use the values of \( v^2 \) from the string simulations [19]: \( v^2 = 0.43 \) in the radiation era and \( v^2 = 0.37 \) in the matter era. The corresponding values of \( \kappa_s \) are, respectively, 0.07 and 0.14. Our estimate for \( \kappa_g \) is \( \kappa_g \sim 1 \), so it seems reasonable to assume that \( \kappa_g > \kappa_s \). The solution of Eq.(5)
is \( r(t) \propto t^{\kappa_g - \kappa_s} \), suggesting that if \( r \) is initially small, it will grow at least until it reaches values \( r \sim 1 \).

An equation similar to (5) can also be written for \( r \gtrsim 1 \), but in this case the results of numerical simulations [19] can no longer be used, and the relative magnitude of \( \kappa_s \) and \( \kappa_g \) cannot be assessed. Order-of-magnitude estimates suggest \( \kappa_s \sim \kappa_g \sim 1 \), and in this paper we shall assume that \( \kappa_g > \kappa_s \), so that \( r(t) \) is driven towards large values, \( r \gg 1 \).

As \( r \) grows and monopoles get closer together, \( M\bar{M} \) annihilation should become important at some point. In any case, the growth of \( r \) should terminate at the value \( r_{\text{max}} \sim \mu/m\delta_s \sim \eta_m/\eta_s \), when the monopole separation is comparable to the string thickness \( \delta_s \). It is possible that annihilations will keep \( r \) at a much smaller value. For example, if monopoles develop appreciable relative velocities along the string, they may frequently run into one another and annihilate. The terminal value of \( r \) cannot be determined without numerical simulations of network evolution; here we shall assume that \( r \gg 1 \).

Self-intersections of long necklaces result in copious production of closed loops. For \( r \gtrsim 1 \) the motion of loops is not periodic, so loop self-intersections should be frequent and their fragmentation into smaller loops very efficient. A loop of size \( \ell \) typically disintegrates on a timescale \( \tau \sim r^{-1/2}\ell \). All monopoles trapped in the loop must, of course, annihilate in the end.

Annihilating \( M\bar{M} \) pairs decay into Higgs and gauge bosons, which we shall refer to collectively as \( X \)-particles. The rate of \( X \)-particle production is easy to estimate if we note that infinite necklaces lose a substantial fraction of their length to closed loops in a Hubble time. The string length per unit volume is \( \sim \xi^{-2} \), and the monople rest energy released per unit volume per unit time is \( r\mu/\xi^2t \). Hence, we can write

\[
\frac{dn_X}{dt} \sim \frac{r^2 \mu}{t^3 m_X},
\]

where \( m_X \sim \epsilon \eta_m \) is the \( X \)-particle mass and we have used Eq.(3).

In the extreme case of \( r \sim r_{\text{max}} \sim \eta_m/\eta_s \), Eq.(3) gives the rate of \( X \)-particle production which does not depend on the string scale \( \eta_s \). It is possible that the evolution of \( r(t) \) is
actually saturated in this regime.

\(X\)-particles emitted by annihilating monopoles decay into hadrons, photons and neutrinos, which contribute to the spectrum of cosmic ultra-high energy radiations. In particular the diffuse flux of ultra-high energy protons can be evaluated as

\[
I_p(E) = \frac{1}{4\pi} \frac{dn_X}{dt} \frac{\lambda_p(E)}{m_X} W_N(m_X, x),
\]

(7)

where \(dn_X/dt\) is given by Eq.(6), \(\lambda_p(E)\) is the attenuation length for ultra-high energy protons due to their interaction with microwave photons and \(W_N(m_X, x)\) is the fragmentation function of X-particle into nucleons of energy \(E = xm_X\).

The fragmentation function is calculated using the decay of X-particle into QCD partons (quark, gluons and their supersymmetric partners) with the consequent development of the parton cascade. The cascade in this case is identical to one initiated by \(e^+e^-\)-annihilation. We have used the fragmentation function in the gaussian form as obtained in MLLA approximation in [20] and [21]. Additionally, we took into account the supersymmetric corrections to the coupling constant \(\alpha_s\) at large \(Q^2\). The details will be described elsewhere. Here we shall give only the explicit form of the fragmentation function we used:

\[
W_N(m_X, x) = \frac{K_N}{x} \exp\left(-\frac{\ln^2 x/x_m}{2\sigma^2}\right),
\]

(8)

where

\[
2\sigma^2 = \frac{1}{6} \left(\ln \frac{m_X}{\Lambda}\right)^{3/2},
\]

\(x = E/m_X, x_m = (\Lambda/m_X)^{1/2}, \Lambda = 0.234 \text{ GeV}\) with the normalization constant \(K_N\) to be found from energy conservation assuming that about 10% of initial energy \((m_X)\) is transferred to nucleons.

For attenuation length of UHE protons due to their interactions with microwave photons we used the calculations described in the book [3].

Note that in our calculations the UHE proton flux is fully determined by only two parameters, \(r^2\mu\) and \(m_X\). The former is restricted by low energy diffuse gamma-radiation.
It results from e-m cascades initiated by high energy photons and electrons produced in the decays of X-particles.

The cascade energy density predicted in our model is

$$\omega_{\text{cas}} = \frac{1}{2} f_\pi r^2 \mu \int_0^{t_0} \frac{dt}{t^3 (1 + z)^4} = \frac{3}{4} f_\pi r^2 \mu t_0,$$

where $t_0$ is the age of the Universe (here and below we use $h = 0.75$), $z$ is the redshift and $f_\pi \sim 1$ is the fraction of energy transferred to pions. In Eq.(9) we took into account that half of the energy of pions is transferred to photons and electrons. The observational bound on the cascade density, for the kind of sources we are considering here, is $\omega_{\text{cas}} \lesssim 10^{-5} \text{eV/cm}^3$. This gives a bound on the parameter $r^2 \mu$.

In numerical calculations we used $r^2 \mu = 1 \times 10^{28} \text{GeV}^2$, which results in $\omega_{\text{cas}} = 5.6 \times 10^{-6} \text{eV/cm}^3$, somewhat below the observational limit. Now we are left with one free parameter, $m_X$, which we fix at $1 \times 10^{14} \text{GeV}$. Note that with this value, the maximum energy of protons is not very high: $E_{\text{max}} \sim 10^{13} \text{GeV}$. The calculated proton flux is presented in Fig.1, together with a summary of observational data taken from ref. [23]. These data are usually interpreted as indicating the presence of a new component at energy higher than $1 \times 10^{10} \text{GeV}$. One cannot claim that our predicted flux gives a good fit to the data for this component, but the discrepancy does not exceed $2\sigma$.

Let us now turn to the calculations of UHE gamma-ray flux from the decays of X-particles. The dominant channel is given by the decays of neutral pions. The flux can be readily calculated as

$$I_\gamma(E) = \frac{1}{4\pi} \frac{dn_X}{dt} \lambda_\gamma(E) N_\gamma(E),$$

where $dn_X/dt$ is given by Eq.(3), $\lambda_\gamma(E)$ is the absorption length of a photon with energy $E$ due to $e^+e^-$ pair production on background radiation and $N_\gamma(E)$ is the number of photons with energy $E$ produced per one decay of X-particle. The latter is given by

$$N_\gamma(E) = \frac{2K}{m_X} \int_{E/m_X}^1 \frac{dx}{x^2} \exp \left( -\frac{\ln^2 x/x_m}{2\sigma^2} \right)$$

(11)
The normalization constant $K_{\pi^0}$ is again found from the condition that neutral pions take away $f_\pi/3$ fraction of the total energy $m_X$.

An important point in our calculations was accounting for the absorption of UHE photons due to $e^+e^-$ production on background radiation. At energy $E > 1 \cdot 10^{10}$ GeV the dominant contribution to the absorption comes from the radio background. The significance of this process was first noticed in [24] (see also book [3]). New calculations for this absorption were recently done [25]. We have used the absorption lengths from this work.

The calculated flux of gamma radiation is presented in Fig. 1 by the curve labelled $\gamma$. One can see that at $E \sim 1 \cdot 10^{11}$ GeV the gamma ray flux is considerably lower than that of protons. This is mainly due to the difference in the attenuation lengths for protons (110 Mpc) and photons (2.6 Mpc [23] and 2.2 Mpc [24]). At higher energy the attenuation length for protons dramatically decreases (13.4 Mpc at $E = 1 \cdot 10^{12}$ GeV) and the fluxes of protons and photons become comparable.

A requirement for the models explaining the observed UHE events is that the distance between sources must be smaller than the attenuation length. Otherwise the flux at the corresponding energy would be exponentially suppressed. This imposes a severe constraint on the possible sources. For example, in the case of protons with energy $E \sim (2-3) \cdot 10^{11}$ GeV the proton attenuation length is 19 Mpc. If protons propagate rectilinearly, there should be several sources inside this radius; otherwise all particles would arrive from the same direction. If particles are strongly deflected in extragalactic magnetic fields, the distance to the source should be even smaller. Therefore, the sources of the observed events at the highest energy must be at a distance $R \lesssim 15$ Mpc in the case or protons.

In our model the distance between sources, given by Eq.(3), satisfies this condition for $r > 3 \cdot 10^4$, while $r_{max} \sim \eta_m/\eta_s$ can be many orders of magnitude larger. This is in contrast to other potential sources, including supeconducting cosmic strings and powerful astronomical sources such as AGN, for which this condition imposes severe restrictions.

The difficulty is even more pronounced in the case of UHE photons. These particles propagate rectilinearly and their absorption length is shorter: $2-4$ Mpc at $E \sim 3 \cdot 10^{11}$ GeV. It
is rather unrealistic to expect several powerful astronomical sources at such short distances. This condition is very restrictive for topological defects as well. The necklace model we introduced here is rather exceptional.

In conclusion, we do not claim that we found a model explaining the observations, but almost.
