Origins of electromagnetic anisotropy in monolayer black phosphorus

Pengke Li (李鹏科)
Department of Physics, University of Maryland, College Park, MD 20742

Contrary to empirical observations, lowest-order $k \cdot p$ theory predicts that monolayer black phosphorus (“phosphorene”) is completely immune to zigzag-polarized optical excitation at the bandgap energy. Using symmetry arguments, we derive a $2 \times 2$ Hamiltonian under the $k \cdot p$ formalism including higher-order corrections, which is used to show that the experimentally-measured band-gap transition with zigzag polarization is dominated by the third order $k \cdot p$ perturbation in the interband optical matrix element, whereas the effects of spin-orbit interaction are negligible in this material, consistent with a trivial orbital diamagnetic contribution to the $g$-factor.

I. INTRODUCTION

Monolayer or few-layer black phosphorus is a 2-dimensional van der Waals layered material with many strong in-plane anisotropic properties. The anisotropy is endowed by the material’s orthorhombic lattice structure, which can be roughly envisioned as a distorted honeycomb lattice with all the bonds parallel to the armchair direction tilted out-of-plane alternatively by approximately $\pm 72^\circ$, such that the otherwise-flat atomic plane is “puckered”, with lattice constants $a_x = 4.376$ Å and $a_y = 3.314$ Å. Consequently, the electronic structure is drastically different for band dispersion along the zigzag and armchair directions, reflecting the underlying geometric symmetry of the system.

Group theory was first used to investigate the band structure symmetry of monolayer black phosphorus and was later applied to incorporate external effects, such as strain, lattice vibration and extrinsic spin-orbit coupling. In Ref. [4], the “method of invariants” was implemented on a multiband Hamiltonian to examine lowest-order interband interactions, providing comprehensive understanding of the physics governing the anisotropy of features in the band structure, optical selection rules, and spin mixing. Monolayer black phosphorus is a semiconductor with a bandgap $\sim 2$ eV near the Brillouin-zone center ($\Gamma$-point), as given computationally by sophisticated DFT+GW calculation and experimentally by photoluminescence spectroscopy. Since most experimentally-probed properties are closely related to the gap-edge conduction and valence states, it is most convenient to adopt a simple model focusing solely on these orbitally-nondegenerate bands, described by a $2 \times 2$ Hamiltonian

$$\hat{H} = \begin{bmatrix} H_c & H_{cv} \\ H_{cv}^\dagger & H_v \end{bmatrix}.$$  \hspace{1cm} (1)

Here, the basis functions are naturally chosen as the gap edge conduction and valence states at the $\Gamma$-point. It is evident from an atomic orbital tight binding model that the conduction (valence) band belongs to the irreducible representation $\Gamma_1^+$ ($\Gamma_2^-$) with $z$-like ($xz$-like) spatial symmetry. As a result, the symmetry of the off-diagonal $H_{cv}$ is given by their direct product $\Gamma_2^- \otimes \Gamma_1^+ = \Gamma_3$, which is $x$-like. Here we follow the convention in Ref. [4] with the $x$, $y$ and $z$ axes corresponding to the armchair, zigzag, and out-of-plane directions, respectively. Relevant analyses from Ref. [4], such as the symmetry behaviors of the $\Gamma$-point irreducible representations and their direct product relations, are organized in the Supplemental Material (SM).

The $x$-like off-diagonal $H_{cv}$ indicates that the gap edge states are directly coupled by the momentum operator $\hat{p}_x$, whereas $\hat{p}_y$ is forbidden by symmetry. This fact can also be seen from a reduced tight binding model under continuum approximation and is consistent with the experimentally-observed strong photoluminescence with polarization along the armchair direction. Surprisingly, the same experiment also demonstrated that the zigzag-polarized photoluminescence is small but certainly nonzero, which is not explained by any lowest-order model. Recently, it was proposed that symmetry-allowed $k$-dependent spin orbit coupling is responsible for the optical transition polarized along $y$, but the argument relies on an unreasonably overestimated spin-orbit parameter. On the contrary, spin-free $ab initio$ calculations show that the optical spectrum of zigzag polarization is indeed finite and increases beyond the bandgap, with amplitude two orders of magnitude smaller than that of the armchair polarization, suggesting the origin of this puzzling observation should be related to higher-order contributions from the $k \cdot p$ interaction.

Earlier attempts to introduce higher order $k \cdot p$ components in the off-diagonal matrix element were made, but only to fit the ultrafast zigzag valence band dispersion. There, quadratic forms like $k^2_{x,y}$ (belonging to the scalar $\Gamma_1^+$ representation) were arbitrarily added into $H_{cv}$. Although their parameters could be chosen as complex values to maintain the necessary time reversal invariance of the Hamiltonian, one cannot ignore the more stringent fact that the underlying spatial symmetry forbids the coexistence of linear and quadratic terms. Hamiltonians constructed with incompatible symmetry may still produce a recognizable eigenspectrum, yet the optical matrix elements derived from it will be seriously flawed.

Note that the $k \cdot p$ Hamiltonian under this symmetry argument should not be confused with the different Hamiltonian constructed from the tight-binding approach. In the latter case, under the continuum approximation, both linear and quadratic terms are allowed
in the off-diagonal matrix element which describes the hopping between atomic sites, rather than perturbative interband coupling as in \( \mathbf{k} \cdot \mathbf{p} \). It is straightforward to verify that a unitary transform of the tight binding Hamiltonian into the band basis at the zone center eliminates any off-diagonal quadratic terms.

The present study aims to resolve any confusion surrounding the aforementioned problem. We start by deriving concise matrix elements of \( \hat{H} \) in Eq. \( (1) \) that capture necessary symmetry-allowed \( \mathbf{k} \cdot \mathbf{p} \) terms up to the third order in perturbation theory, including spin-orbit coupling. From the resulting interband optical matrix element, together with the band dispersion, we calculate the polarization-dependent dipole interaction strength as a function of the photon energy. The underlying physics of the optical anisotropy across the bandgap, especially of the weak but finite optical transition with linear polarization along the zigzag orientation, is shown to be dominated by the third-order \( \mathbf{k} \cdot \mathbf{p} \) interband matrix element, whereas the influence of spin-orbit coupling is negligible.

At the end of the paper, the interband optical matrix elements are also used to investigate the small diamagnetic correction of the \( g \)-factor induced by orbital magnetic moment from the single-particle bandstructure.

## II. INTERBAND COUPLING

We consider symmetry-allowed terms in \( H_{\text{CV}} \) up to third order using the method of invariants,\(^\text{13}\) including invariant components of \( k_x \), \( k_xk_y^2 \) and \( \sigma_zk_y \) (the other \( x \)-like third-order term \( k_x^3 \) is not considered, as explained at the end of this section).\(^\text{13}\) The coupling between the conduction and valence bands is then constructed as

\[
H_{\text{CV}} = iP_kx + iP_3k_xk_y^2 + \alpha \sigma_zk_y,
\]

with three parameters \( P = 4.6 \text{ eVÅ}, \ P_3 = -16 \text{ eVÅ}^3 \), and \( \alpha = -5.0 \text{ meVÅ} \), calculated from \textit{ab initio} wavefunctions using the \textsc{Quantum ESPRESSO} package.\(^\text{13}\) Note that polynomial fits to the \textit{ab initio} band dispersion cannot be used to reliably extract these parameters, especially for the higher-order \( P_3 \) and the relatively small \( \alpha \), whose contributions to the dispersion relation are negligible (see next section).

Two different schemes can be implemented to calculate these parameters, strictly following the definition of the \( \mathbf{k} \cdot \mathbf{p} \) formalism.\(^\text{5}\) The values given here are obtained by projecting band edge wavefunctions at small but nonzero \( \mathbf{k} \) onto those at the \( \Gamma \) point, and the resulting off-diagonal term multiplied by \( E_{\text{g}} \) equals the corresponding components in \( H_{\text{CV}} \). In a different approach, we take advantage of the plane-wave basis of the wavefunctions and directly evaluate the matrix element of the momentum operators between the states at the \( \Gamma \)-point, resulting in parameters \( \sim 10\% \) larger than those given by the first method. We have also verified that these values are robust against variation in the details of \textit{ab initio} calculation inputs (such as the types of density functional and pseudopotential, variation in lattice constants, etc). Details of the \textit{ab initio} process used, as well as the calculation of these three parameters, are included in SM\(^\text{13}\). In the following we elaborate the origins of the three terms in Eq. \( (2) \).

The first term \( iP_kx \) arises from the lowest order \( \mathbf{k} \cdot \mathbf{p} \) perturbation,

\[
\hat{H}_{\mathbf{k} \cdot \mathbf{p}} = \frac{\hbar}{m_0} \mathbf{k} \cdot \mathbf{p} = \frac{\hbar}{m_0} (k_x \hat{p}_x + k_y \hat{p}_y).
\]

Since only the \( x \) component is symmetry-allowed, we have \( P = \frac{\hbar}{m_0} \langle \Gamma^- | \hat{p}_x | \Gamma^+_2 \rangle \), as shown in Fig.1(a). Similar to most other semiconductors, \( P \) is close to the nearly-free electron value \( \pi \hbar^2 / (m_0 a_x) \).\(^\text{20}\)

The second term \( iP_3k_xk_y^2 \) originates from the third order \( \mathbf{k} \cdot \mathbf{p} \) perturbation via three types of pathways as shown in Fig.1(b), depending on the sequence of the \( \hat{p}_x \) and the two \( \hat{p}_y \) operators. For example, the panel on the left hand side represents the path

\[
\hat{H}_{\mathbf{k} \cdot \mathbf{p}} = \frac{\hbar^3}{m_0^2} \sum_{r_z, r_z'} \langle \Gamma^-_r | \hat{p}_x | \Gamma^+_2 \rangle \langle \Gamma^+_2 | \hat{p}_y | \Gamma^-_r \rangle \langle \Gamma^-_r | \hat{p}_y | \Gamma^+_2 \rangle \langle \Gamma^-_r | \hat{p}_x | \Gamma^+_2 \rangle k_xk_y^2,
\]

in which the summation is over all intermediate states with \( \Gamma^-_r (xyz) \) and \( \Gamma^+_2 \) symmetries, except the highest valence band. Similarly, the other two panels in Fig.1(b)
represent paths involving intermediate states belonging to \( \Gamma^+_1(yz), \Gamma^+_1 \) and \( \Gamma^+_4 \).

The spin-orbit term \( \alpha \sigma \cdot k_y \) has two comparable contributions as shown in Fig. (1c). First of all, there is the direct \( k \)-dependent spin-orbit coupling

\[
\hat{H}^k_{\text{SO}} = \frac{\hbar^2}{4m_0^2c^2} \nabla V(r) \times k \cdot \sigma
\]

(5)

\[
= \frac{\hbar^2}{4m_0^2c^2} \left[ \frac{\partial V}{\partial x} k_y - \frac{\partial V}{\partial y} k_x \right] \sigma_z + \frac{\partial V}{\partial z} (k_x \sigma_y - k_y \sigma_x),
\]

in which only the first term (proportional to \( \frac{\partial V}{\partial x} k_y \sigma_z \)) has the required \( x \)-like symmetry and couples the conduction and valence bands, as shown by the left panel in Fig. (1c). In addition, there are second-order perturbation paths via the \( y \)-component of \( \hat{H}_{k \cdot p} \) (\( \Gamma^+_2 \), \( y \)-like) and the \( \sigma_z \) component (\( \Gamma^+_3 \), \( xy \)-like) of the \( k \)-independent spin-orbit coupling term

\[
\hat{H}_{\text{SO}} = \frac{i\hbar}{4m_0^2c^2} \nabla V(r) \times \vec{p} \cdot \sigma.
\]

(6)

The combination of the two operators has a net symmetry \( \Gamma^+_2 \otimes \Gamma^+_4 = \Gamma^+_3 \), and the intermediate states involved belong to \( \Gamma^+_3 \) or \( \Gamma^+_1 \).

The strength of the spin-orbit term can be estimated from the ratio between the \( k \)-linear operators \( \hat{H}_{\text{SO}} \) and \( \hat{H}_{k \cdot p} \), which is around \( V/4m_0c^2 \), with \( V \) on the order of 1 keV for phosphorus core electron levels (in the region where the potential varies most drastically\(^{21} \)), and \( 4m_0c^2 \approx 2 \) MeV. As a result, \( |\alpha| \sim 10^{-3}P \), consistent with the values we obtained. For comparison, the neighboring elemental material (Si) has \( P \approx 9 \) eV\( \cdot \)A and \( \alpha = 8.6 \) meV\( \cdot \)A at the conduction band minimum\(^{22} \).

Despite their higher-order nature, both \( iP k_x k_y \) and \( \alpha \sigma \cdot k_y \) terms in the off-diagonal Hamiltonian matrix element lead to a nonzero interband optical transition with polarization along \( y \) (zigzag), since their relevant matrix elements of the momentum operator \( \frac{\partial}{\partial k} \nabla_k H \) are nonzero. However, direct comparison with the experimental spectra requires integration of \( \partial H_{c,v} / \partial k_y \) over \( k \)-points with the same transition energy in the Brillouin zone. Because of the ultra-flat valence band in phosphorene, the third-order term \( P k_x k_y^2 \) dominates over the linear spin-orbit term \( \alpha \sigma \cdot k_y \), as we will thoroughly discuss in Sec. IV.

The same consideration justifies our neglect of the symmetry-allowed term \( k_y^3 \), as mentioned at the beginning of this section, since \( \partial k_x / \partial k_y \) vanishes. This third order term does contribute to the \( x \)-polarized dipole transition, but is negligible compared with the lowest order \( k_x \)-linear term.

### III. DIAGONAL MATRIX ELEMENTS

Both \( H_c \) and \( H_v \) have scalar symmetry (\( \Gamma^+_1 \)). By capturing the higher-order influence from remote bands due

![FIG. 2. Band structure close to the gap, along the \( k_x \) (armchair) and \( k_y \) (zigzag) directions. The blue curves are the spectra of the 2 \( \times \) 2 Hamiltonian detailed by Eqs. (1), (2), (7) and (8). Red circles mark the \( ab \) initio spectra. The forbidden gap is truncated for better presentation of the features of the bands. Inset: zoom in of the valence band at small \( k_y \), highlighting the unusual ‘electron’-like dispersion closest to the \( \Gamma \)-point.

\[
\begin{align*}
H_c &= E_g + A_c k_x^2 + B_c k_y^2, \\
H_v &= A_v k_x^2 + B_v k_y^2 \left[ \frac{C_v}{1 + (k_y/k_t)^2} - C_v + 1 \right].
\end{align*}
\]

(7) (8)

The underlying physics of the coefficient parameters and the unusual form of \( H_v \) beyond quadratic order are explained in the following. First of all, the scalar symmetry is evident in Eqs. (7) and (8) due to the even powers of \( k_x \) and \( k_y \). Here, due to the well-known issue of band gap underestimation in the DFT process, the value of the \( \Gamma \)-point band gap used is \( E_g = 0.7 \) eV\(^{11,29} \), which is smaller than the \( \sim 2 \) eV given by more sophisticated DFT+GW calculation\(^{9,10,11,10} \). However, this quantitative issue doesn’t affect the fundamental physics we focus on in this study\(^{11} \).

Along the armchair (\( k_x \)) direction, \( A_{c,v} \) quantify the influence from remote bands on top of the free electron dispersion\(^{9} \) and together with the \( iP k_x \) component in \( H_{c,v} \), determine the conduction and valence band curvatures at the zone center. With our \( ab \) initio results of the effective masses along \( k_x \) being \( m_x^* = 0.148m_0 \) and \( m_y^* = -0.132m_0 \), the dispersion coefficients \( A_{c,v} \) are calculated according to

\[
A_c + \frac{P^2}{E_g} = \frac{\hbar^2}{2m_x^*}, \quad \text{and} \quad A_v - \frac{P^2}{E_g} = \frac{\hbar^2}{2m_y^*},
\]

(9)

giving \( A_c \approx -5.2 \) eV\( \cdot \)A\(^2 \) and \( A_v \approx 2.5 \) eV\( \cdot \)A\(^2 \). For comparison, the off-diagonal \( k \cdot \vec{p} \) coupling contributes a dispersion coefficient \( \frac{P^2}{E_g} \approx 29.6 \) eV\( \cdot \)A\(^2 \), which is larger than the amplitudes of \( A_{c,v} \), suggesting that the interband \( k \cdot \vec{p} \)
coupling directly between conduction and valence bands is primarily responsible for the relatively small effective masses in this direction.

On the other hand, the band curvatures along $k_y$ (zigzag) are dominated by the $k_y$-related terms of the diagonal elements, whereas the off-diagonal interband coupling plays a minor role. With an *ab initio* value of the conduction band effective mass $m^*_c \approx 1.18 m_0$, we get $B_c = \frac{k_y^2}{2m^*_c} - E_c \approx 3.2 \text{ eV}\cdot\text{Å}^2$. For comparison, the contribution of the spin-orbit interband coupling to the band dispersion in this direction is $\alpha^2 \approx 3.6 \times 10^{-5} \text{ eV} \cdot \text{Å}^2$, orders of magnitude smaller. This further verifies our previous argument that the value of $\alpha$ cannot be reliably extracted by functional fitting of the band structure.

The valence band dispersion along $k_y$ (zigzag) given by the second term in Eq. (8) is distinct from conventional quadratic dispersion, in that the band is ‘electron’-like with slightly positive curvature close to the origin, but eventually bends downward at larger $k_y$ (see inset in Fig. 2), as observed in other *ab initio* calculations.\cite{9,17,23}

This behavior is due to the gradually diminishing repulsion from a $\Gamma$ lower valence band as $k_y$ increases, resulting in the ‘camel back’-shaped dispersion relation and the large average effective mass in this direction. Our expression of $H_v$ is simplified from Eqs. (17) and (19) in Ref. 4 that summarize this unusual behavior of band dispersion, as seen from the denominator $1 + (k_y/k_x)^2$ of the first term in the parenthesis in Eq. (8). By fitting the *ab initio* valence band dispersion along $k_y$, we get $B_v = 0.43 \text{ eV} \cdot \text{Å}^2$, the unitless $C_v = 7.6$, and $k_t = 0.23 \text{ Å}^{-1}$ quantifies the extension of the ‘electron-like’ behavior along $k_y$. At small $k_y$, the dispersion is approximately $B_v k_y^2$ with an effective electron-like mass $8.8 m_0$, whereas at large $k_y$, the dispersion is approximately $B_v(1 - C_v) k_y^2$ with an effective hole-like mass $-1.33 m_0$. Note that here the band curvature only corresponds to the concept of effective mass at a certain $k$ point, which should not be confused with the experimentally-determined effective mass resulting from a $k$-space averaging over participating states.

**IV. BAND STRUCTURE AND DENSITY OF STATES (DOS)**

With Eqs. (2), (7) and (8), the $2 \times 2$ Hamiltonian Eq. (1) can be analytically diagonalized with the spectrum shown in Fig. 2. It perfectly matches the *ab initio* band structure close to the gap edge, including the ultraflat feature of the valence band along $k_y$ as shown in the inset. The turning point of $E_v(k_x = 0, k_y)$ is around $k_y = 0.06 \text{ Å}^{-1}, \sim 7\%$ from $\Gamma$ to the zone edge, indicating that states with large $k_y$ might play important roles in transport or optical phenomena. It is easy to verify that, within the energy range of our interest, the third order term $iP_3 k_x k_y^3 \approx \alpha k_y$ is negligible.

The constant-energy surface contours of the valence and conduction bands, and their energy difference across the bandgap are given in Fig. 3(a)-(c), respectively. The valence band contour is in an oval stadium shape with a stronger anisotropy than the elliptical shape of the conduction band isoenergetic contours. The valence band absolute maxima are not at the zone center but rather at two points along the $k_x$ axis, reproducing the dispersion shown in the inset of Fig. 2.

The densities of states (DOS) of the two bands as functions of the energy can be calculated from the 2D dispersion relation according to

$$\text{DOS}_{c,v}(E) = 2 \int d^2 k \delta[E - E_{c,v}(k)],$$

where the prefactor $2$ accounts for spin degeneracy. Similarly, the joint density of states (JDOS) is calculated from

$$\text{JDOS}(E) = 2 \int d^2 k \delta[E - E_c(k) + E_v(k)].$$

The DOS and JDOS are presented in Fig. 3(d)-(f). The DOS of the conduction band is a constant around $0.021 \text{ eV}^{-1}\text{Å}^{-2}$. Due to the smaller orientation-averaged
effective mass, it is lower than the 2D free electron DOS of $\frac{m_0}{m_0'} = 0.042$ eV$^{-1}$Å$^{-2}$. In contrast, the DOS of the valence band saturates at lower energy, but approaches divergence near the band edge. Since the DOS is inversely proportional to $|\nabla_k E_n|$, this ‘singularity’-like feature is the result of the unusually flat $k_y$ dispersion at the band edge, and is inherited by the JDOS close to the band gap edge.

V. MOMENTUM MATRIX ELEMENT AND DIPOLE STRENGTH

The interband optical matrix element could be calculated from the $2 \times 2$ Hamiltonian as $\langle \Gamma_{4c} | \frac{\hbar}{\mathbf{k}} \nabla \mathbf{k} \mathcal{H} \Gamma_{7c} \rangle$. For simplicity, we take out the constant factor $\frac{\hbar}{\mathbf{k}}$ and examine the operator $\hat{\pi}_{x,y} = \partial \mathcal{H}/\partial k_{x,y}$. It is straightforward to see that $\langle \Gamma_{4c} | \hat{\pi}_x \Gamma_{7c} \rangle = i(2 P_3 k_{3y}^2)$ and $\langle \Gamma_{4c} | \hat{\pi}_y \Gamma_{7c} \rangle = \alpha_0 k_x k_y$, both including a constant term and a second-order term. Here, we examine the contributions of each of these four terms to the optical dipole strengths as functions of the photon energy $E_{ph}$, by integration over $\mathbf{k}$ points with the same energy difference between the conduction and valence bands. For the two constant terms, the dipole interaction strengths are simply $P^2$ and $\alpha^2$ multiplied by the JDOS,

\begin{align}
D^x_p(E_{ph}) &= 2 P^2 \int d^2 k \delta[E_{ph} - E_c(k) + E_v(k)], \quad (12)
D^y_\alpha(E_{ph}) &= 2 \alpha^2 \int d^2 k \delta[E_{ph} - E_c(k) + E_v(k)], \quad (13)
\end{align}

where both expressions are in units of eV. Similarly, for the $\mathbf{k}$-dependent second order terms, we have

\begin{align}
D^x_3(E_{ph}) &= 2 P^2 \int d^2 k \ k^2 \delta[E_{ph} - E_c(k) + E_v(k)], \quad (14)
D^y_3(E_{ph}) &= 2 P^2 \int d^2 k \ k \ k_y \delta[E_{ph} - E_c(k) + E_v(k)], \quad (15)
\end{align}

where the subscript ‘3’ in $D^x_3, y_3$ indicates their origin in the third order $\mathbf{k} \cdot \mathbf{p}$ perturbation term.

These four quantities are plotted in Fig. 4 as functions of $E_{ph}$ beyond the band gap. As expected, $D^x_p$ and $D^y_\alpha$ are lowest order and vary only slightly throughout the energy range of our interest, in contrast with the monotonically increasing higher order $D^x_3, y_3$. For armchair ($x$) polarization, $D^x_p$ dominates over $D^y_3$, as expected. Although it is much weaker, the transition with polarization along $y$ (zigzag) is governed by $D^y_3$, originating from the third order $\mathbf{k} \cdot \mathbf{p}$ perturbation paths in Fig. 1(b). The contribution of $D^y_3$ due to spin-orbit coupling is orders of magnitude smaller, once the photon energy is slightly beyond $E_g$. This is not only a consequence of the weak spin-orbit coupling of phosphorus, but also because interband transition at higher photon energy involves states with relatively large $k_y$, along which the dispersion is very flat. It is easier to understand this point from a quantitative estimation, with the help of the energy contour in Fig. 3(c): for photon energy 0.7 eV beyond the bandgap at around $\mathbf{k} = (0.05\text{Å}^{-1},0.3\text{Å}^{-1})$, we have $2P_3 k_x k_y \approx 0.48$ eV·Å$\gg |\alpha|$.

The total dipole strengths in the two orthogonal directions are given by the markers in Fig. 4. $D^{y_3}$ exactly equals the sum of $D^y_p$ and $D^y_3$, yet mostly overlaps with the latter, as we analyze. $D^x$ is slightly smaller than the sum of $D^x_p$ and $D^x_3$, due to the cross product of $P_y$ and $P_y k_y^2$ in $|\langle \hat{\pi}_x \rangle|^2$. At high photon energy, the ratio between $D^{y_3}$ and $D^{x_3}$ is close to $\sim 1\%$, which is consistent with the experimental observation of photoluminescence from decay of direct excitons(23) whose wavefunction in the 2D monolayer is spatially localized along the zigzag direction(23) and involves relatively large $k_y$ components in reciprocal space.

VI. $g$-FACTOR

The momentum operator $\hat{\pi}_{x,y}$ could also be used to evaluate the orbital magnetic moment contribution to the Landé $g$-factor under out-of-plane magnetic field(25)

$$\Delta g = \frac{2}{im_0} \frac{m_0^2}{\hbar^2} \sum_{n,n'} \frac{|\langle n | \hat{\pi}_x | n' \rangle \langle n' | \hat{\pi}_y | n \rangle - |\langle n | \hat{\pi}_y | n' \rangle \langle n' | \hat{\pi}_x | n \rangle|}{E_n - E_{n'}}. \quad (16)$$

Within a two-band Hamiltonian, $\Delta g$ is the same for both the conduction and valence states. Letting $|n\rangle = |\Gamma_{4c}\rangle$ and $|n'\rangle = |\Gamma_{7c}\rangle$, we have

$$\Delta g = \frac{4 m_0 (P + P_3 k_y^2) \alpha}{E_g} \approx \frac{4 m_0 P \alpha}{\hbar^2} E_g = -0.017. \quad (17)$$

![Figure 4](image-url)
It is straightforward to apply Eq. (10) to energetically remote states beyond the $2 \times 2$ model to calculate the complete single-particle correction to the $g$-factor. Only those states with relevant symmetries need to be taken into account. On one hand, the conduction (valence) state $|\Gamma_{4c}\rangle (|\Gamma_{4v}\rangle)$ can couple to any other states with $\Gamma_2$ ($\Gamma_4$) symmetry via $\hat{p}_z k_z$ and $\partial V / \partial y k_y$, as demonstrated by Fig. 1(a) and the left panel of Fig. 1(c), respectively. For each of these remote states, interband coupling parameters similar to $P$ and $\alpha$, as well as the energy difference, can be calculated in the same way using the $ab\ initialo$ wavefunctions, and then their contribution to the $g$-factor correction is obtained using Eq. (17). On the other hand, as shown in the right panel of Fig. 1(c), one should not ignore the fact that $|\Gamma_{4c}\rangle (|\Gamma_{4v}\rangle)$ could also couple to remote states with $\Gamma_1^0$ ($\Gamma_1^{-}$) symmetry, via the $\hat{k} \cdot \hat{p}$ operator $\hat{p}_y k_y$, together with the $k$-dependent spin orbit coupling component in Eq. (5) proportional to $\partial V / \partial y k_y$. Although these two operators are irrelevant to the gap edge coupling matrix element $H_{cv}$ in our $2 \times 2$ model, they contribute similar $g$-factor correction as their corresponding orthogonal counterparts.

Summing over the contribution from all symmetry-related bands, the orbital magnetic moment induced to different multilayer systems under strong-correlation condition, it is suggested that electron-electron interaction could substantially modify the $g$-factor.\textsuperscript{10}
