Quantum coherence plays an essential role in diverse natural phenomena and technological applications. The unavoidable coupling of the quantum system to an uncontrolled environment incurs dissipation that is often described using the secular approximation. Here we probe the limit of this approximation in the rotational relaxation of molecules due to thermal collisions by using the laser-kicked molecular rotor as a model system. Specifically, rotational coherences in \( \text{N}_2\text{O} \) gas (diluted in \( \text{He} \)) are created by two successive nonresonant short and intense laser pulses and probed by studying the change of amplitude of the rotational alignment echo with the gas density. By interrogating the system at the early stage of its collisional relaxation, we observe a significant variation of the dissipative influence of collisions with the time of appearance of the echo, featuring a decoherence process that is well reproduced by the nonsecular quantum master equation for modeling molecular collisions.
Energy transfers through quantum coherences are key mechanisms in natural phenomena and technological applications, such as human vision, light-harvesting complexes, quantum heat engines, and quantum information and computing. The understanding of the long-lived coherence involved in these phenomena requires a detailed modeling of the system-bath interactions beyond the so-called secular and/or Markovian approximations. Despite continuous theoretical progress on understanding nonsecular dynamics in the last decades, convincing experimental observations are still lacking, in particular when they manifest through collision-induced processes. More generally, understanding how collisions between molecules change their translational and rotational motions is a fundamental problem of physics that has numerous practical implications. Indeed, most real gas media being at non-negligible pressure, intermolecular interactions affect many observable quantities. At thermodynamic equilibrium, they play a key role in the shape of light-absorption and light-scattering spectra and in the transports of mass and energy, for instance. When the system has been brought out of equilibrium by some external action (for example one or several resonant or nonresonant electromagnetic excitations or a plasma discharge), collisional processes are often the main channel inducing decoherence and transfers among populations bringing it back to equilibrium.

Collisional effects have been extensively studied in the spectral domain by looking at the shape of various absorption features. In the time domain, it has been recently shown that the decay of alignment echoes induced by two laser kicks permits time-resolved measurements of collision-induced rotational changes at short time scales. So far, all quantum models used for the calculation of the effects of decoherence processes due to intermolecular forces are based upon the Markovian and secular approximations. These allow to obtain the density matrix describing the evolution of the system when coherences (i.e., nondiagonal elements of the density matrix) have been created (for example by laser pulse(s), as in the present work). Recall that the Markov approximation assumes that all collisions are complete and un-correlated (no memory effects in the system-bath history) while the secular approximation assumes that the delay at which the system is observed after the creation of the coherences is much greater than the periods of oscillation of the coherences.

Here we provide the experimental and theoretical evidence that rotational alignment echoes enable to probe an open molecular system at the early stage of its collisional relaxation where the secular approximation breaks down. These echoes occur after molecules have been suddenly aligned by two successive nonresonant laser excitations. A first short pulse, P1, impulsively aligns some of the molecules along its polarization direction thanks to the anisotropy of the molecular polarizability. This results in a peak in the alignment factor (cos^2(θ)) (t) (θ being the angle between the molecule axis and the laser polarization direction and (t) denoting the quantum expectation value) that quickly vanishes due to rotational dephasing. After a delay τ1, a second pulse, P2, is applied that induces a rephasing process leading to the creation of an echo in the alignment factor at time Δt = 2τ1 after P1. The decay, with pressure, of the echo is studied in N2O–He gas mixtures for various delays τ1. The experiments show that the dissipation of the echo is all the more rapid when the delay is long, a result in contrast with the secular model predicting delay-independent results. On the other hand, very good agreement between measurements and calculations is obtained when a nonsecular approach is used.

**Results**

**Experiments.** The experiment is implemented with the setup depicted in Fig. 1 and further described in the Methods section. After the molecules have been aligned by two laser kicks, the anisotropy of the medium resulting from the reorientation of the molecules is interrogated by a probe pulse. A detection is performed so that the measured signal is directly proportional to the convolution of (cos^2(θ)) (t) – 1/3) with the temporal envelope of the probe, where 1/3 is the alignment factor obtained when molecules are randomly oriented. Figure 2a exemplifies the echo features observed in the alignment signal of linear molecules at low pressure. Like any other echo phenomenon, the dominant echo response appears at the symmetric position of P1 with respect to P2 along the time axis. It is followed by higher-order and imaginary echoes and revivals. All these structures exhibit an asymmetric temporal shape consisting of a peak resulting from the alignment of the molecules along the polarization of the pump field, and a dip associated with a delocalization of the molecular axes within a plane perpendicular to the field vector.

It is only very recently that the collisional dissipation of echoes has been studied by analyzing the evolution of their amplitudes for various delays at fixed gas density. The interest of this approach to probe the dissipation of the alignment under high-pressure conditions where standard alignment revivals cannot be used was demonstrated in ref. Indeed, revivals restrict the probing of the system to specific times that are tied to the moment of inertia of the molecule. On the contrary, the rotational echo provides much more flexibility, since its time of appearance can be tuned at will by adjusting the delay between P1 and P2. The echo is therefore particularly well suited for interrogating the dynamics of the system at early times, much before the first revival appears. As shown in Fig. 2b, we here look at the echoes from a point of view different from that used in refs. and study the reduction of their density-normalized amplitudes “S” with increasing pressure for fixed values of τ1. Note that all results presented from now on have been recorded in high-pressure (up to 25 bar) mixtures of N2O gas diluted in 96% of helium. The high concentration of helium, which has been chosen for its weak nonlinear optical properties, allows overcoming the nonlinear propagation effects that would take place in high-density pure molecular gases of the same nature. A first indication of the enriched information brought by the echo with respect to the revivals is revealed by Fig. 2c, which shows measured amplitudes of five echoes and two revivals as a function of the density multiplied by the time of appearance of the considered alignment structure (i.e., the echo or the nth revival). Obviously, the efficiency with which collisions reduce the alignment amplitude is the same for the half and full revival (at 20.2 and 40.4 ps), while it varies significantly for the echoes observed between τ1 = 1.61 and 8.58 ps. By repeating the measurements of Fig. 2c for several delays and gas densities, we have been able to extract (see the Methods section) density-normalized characteristic time constants of the echo amplitude decay from exponential fits (see Fig. 2c). The values reported in Fig. 3 show that the echo decay is slow at short times and becomes faster as the delay increases, before a plateau is reached around 2τ1 = 10 ps. In the plateau region, the echo and the revival share about the same density-normalized characteristic decay time. Note, for comparison, that the mean time interval between successive N2O–He collisions, obtained for the intermolecular distance of 3.5 Ångström where the N2O–He potential is significant (see Supplementary Note 1), is of 70 ps.amagat.
Model. In order to explain the difference between the short-time and long-time dynamics, we performed numerical simulations of the alignment signal in the presence of collisional dissipation. Starting from equilibrium before the pulses, where the density operator \( \rho(t < 0) \) is Boltzmannian and diagonal with respect to the rotational quantum numbers \( J \) (principal) and \( M \) (magnetic), the evolution for \( t \geq 0 \) is obtained from the Liouville-von Neumann equation:

\[
\frac{d\rho}{dt}(t) = -\frac{i}{\hbar} [H_0 + H_L(t), \rho(t)] + \left( \frac{d\rho(t)}{dt} \right)_{\text{Coll,}}.
\]

(1)

where \( \hbar \) is the Planck constant divided by \( 2\pi \), \( H_0 \) is the free rotational Hamiltonian, and

\[
H_L(t) = -\frac{1}{4} E^2(t) \Delta \alpha \cos^2 \theta
\]

(2)

describes the nonresonant interaction of the molecule with the linearly polarized field (up to an irrelevant term that does not multiply the direction cosine operator \( \cos^2 \theta \)), with \( \Delta \alpha = \alpha_{ij} - \alpha_i \) the anisotropic polarizability and \( E(t) \) the temporal envelop of the laser pulse. Note that, in principle, the contribution of the permanent dipole moment of \( \text{N}_2\text{O} \) should be included in Eq. (2). However, since the excitation field used in the experiment (at 800 nm) oscillates with a period (2.7 fs) much smaller than that of the rotation of the molecule for the thermally populated levels, the associated contribution to Eq. (2) averages out. Assuming a Markovian model of collisions (valid here because, as discussed in the Supplementary Note 1, \( \text{N}_2\text{O} \) and He interact very slowly and in a very limited range of intermolecular distance\(^{20}\)), and neglecting all radiative decays since they occur on a much longer time scale, the matrix elements of the dissipation term read

\[
\left( \frac{d\rho_{ij}(t)}{dt} \right)_{\text{Coll}} = -d \sum_{f} \Lambda_i^{ij,f} \rho_{ij}(t),
\]

(3)

where \( i \) and \( j \) denote the rotational states \( |J,M\rangle \) of the system and \( \Lambda^{ij,f} \) are the density-normalized relaxation matrix elements.

Break down of the secular approximation. In a first step, we use the so-called Bloch model in which dissipative effects are treated within the Markovian and secular approximations (further discussed in the Supplementary Notes 1 and 2, respectively). This corresponds to neglecting all elements of the relaxation matrix responsible for transfers among coherences (nondiagonal terms of \( \rho \) and between populations (diagonal elements of \( \rho \)) and coherences. Only the \( \Lambda_{j,j}^{ij,f} \) and \( \Lambda_{i,i}^{ij,f} \) terms are then kept which are directly related to the rates of population transfer from \(|J,M\rangle\) to \(|J',M'\rangle\) (see ref.\(^{21}\) and Supplementary Note 3), including inelastic (\( J \)-changing) and elastic reorienting (\( J \)-conserving, \( M \)-changing) processes, as well as the pure dephasing of the coherence which describes the effect of elastic collisions that interrupt the phase of the molecule without quenching it. Under these approximations, the equation driving the decay of the coherences (i.e., for \( i \neq j \)) becomes

\[
\left( \frac{d\rho_{ij}(t)}{dt} \right)_{\text{Secular}} = -d \Lambda_{ij}^{ij} \rho_{ij}(t)
\]

(4)

The diagonal elements \( \Lambda_{j,j}^{ij} \) have been estimated for \( \text{N}_2\text{O} \)-He at room temperature (see the Supplementary Note 3.1) using the infinite order sudden approximation (IOSA). The calculations show that all these terms are positive, practically independent of \( i \) and \( j \) and equal to 0.013 ps\(^{-1}\) amagat\(^{-1}\). This
means that the echo decay within the secular approximation is independent of the delay. As shown by the simulations represented by the black dashed line in Fig. 3, the secular theory well reproduces the observed decays of the echoes in the plateau region beyond about $2\tau_{12} = 10$ ps with a density normalized time constant of $1/0.013 = 76$ ps amagat. In contrast, the secular model does not capture the weaker efficiency of collisions at shorter times and the fact that the decrease of the echo amplitude with increasing density is here all the more slow when the delay is short. This observation seriously questions the validity of the secular approximation during the early dynamics of the system.

For a simple (but realistic) picture of the limits of the secular approximation, let us assume that coherences have been instantaneously generated by a laser pulse at $t = 0$. This creates nonzero nondiagonal elements $\rho_{JM,V}M(t=0^-)$ between states $|J,M\rangle$ and $|J',M\rangle$, which, in the absence of collisions, then evolve with time according to $\rho_{JM,V}M(t) = \rho_{JM,V}M(t=0^-) \exp[-i(E_J - E_{J'})t/\hbar]$, with $E_J$ and $E_{J'}$ the corresponding rotational energies. Let us now assume that collisions induce transfers between coherences and, in particular, from $\rho_{J,M,J,M}(t)$ to $\rho_{J,M,J',M}(t)$ with a real valued rate constant.

Under some approximations presented in the Supplementary Note 3, it can be shown that the relative change of $\rho_{J,M,J,M}(t)$ due to transfers from $\rho_{J,M,J,M}(t)$ at time $t$ after the laser pulse is

$$\text{Re} \left[ \frac{\Delta \rho_{J,M,J,M}(t)}{\rho_{J,M,J,M}(t)} \right] = B \text{sinc} \left( \frac{\omega_{J,M,J,M} - \omega_{J',M}}{\hbar} t \right),$$

where $\text{Re}[\ldots]$ denotes the real part, $B$ is a constant, $\text{sinc}[\ldots]$ designates a cardinal sine, and $\omega_{J,M,J',M} = (E_J - E_{J'})/\hbar$. It is obvious from Eq. (5) that, as $|\omega_{J,M,J,M} - \omega_{J',M}|t$ gets larger than a few times $\pi$, the transfers between coherences become negligible when compared to the total loss. Note that the imaginary part of $\Delta \rho$ exhibits the same behavior. In order to be more quantitative, let us consider the case of $N_2O$. Since only $\rho_{JM,J',M}(t)$ with $J = J' \pm 2$ contribute to the echo amplitude (see Methods section), we below focus on such elements and limit ourselves to the most populated state $J_0 = 15$ at $T = 300$ K. The quantity in Eq. (5) is plotted in Fig. 4 for $J_0 = 15$, $J_0 = 17$, $J_1 = J_1 + 2$ and $J_1 = J_1$, 17, 19, 21, and 23 (we keep $|J_0 - J_1|,$ even because of the collisional selection rule, see the Supplementary Note 3.2), where all values have been normalized to unity at $t = 0$. As can be seen, transfers between coherences indeed decrease rapidly. They are significant before about 5 ps and practically negligible above 10 ps, a delay beyond which the secular approximation thus becomes valid, a behavior qualitatively consistent with the difference observed at short times between the experimental results and the secular predictions in Fig. 3.

---

**Fig. 2 Rotational structures of N₂O aligned by two laser kicks.** a Alignment signal recorded in pure N₂O gas at low pressure by scanning the temporal delay between the first aligning pulse $P_1$ (at $t = 0$) and the probe pulse over slightly more than the full rotational period $T_R = 40.4$ ps of the molecule. The peaks identified by $P_1$ and $P_2$ correspond to the transient alignment signals produced by the two pulses separated by the delay $\tau_{12}$. The main echo is generated at $t = 2\tau_{12}$, with the secondary echo observable at $t = 3\tau_{12}$, and the imaginary echo produced at $T_R/2 - \tau_{12}$ (equivalent features also appearing at times shifted by $+T_R/2$). In addition to echoes, other transients corresponding to the standard half and full alignment revivals of $P_1$ (at $T_R/2 + \tau_{12}$ and $2\tau_{12}$) are also observed. b Alignment traces of N₂O diluted in He measured at various densities around the main echo at $2\tau_{12}$ for $\tau_{12} = 2.18$ ps. The amplitudes $S$ of the alignment structures are measured from peak to dip. c Amplitudes of the half revival (open red circles), full revival (full blue circles), and of the main echo for different values of the delay $\tau_{12}$ versus the gas density $d$ multiplied by the time of observation $t_R$ ($T_R/2$ or $T_R$) and $2\tau_{12}$ for the revivals and echo, respectively, expressed in picosecond amagat (ps.amagat, with 1 amagat $= 2.687 \times 10^{22}$ mol.$^{-3}$ units). The lines indicate the best exponential fits.
Successful nonsecular predictions. In order to go further, computations of the echo decays have been carried by solving Eqs. (1)–(3) now keeping all collisional transfers channels and thus accounting for secular and nonsecular terms. Equation (3) thus becomes

$$\frac{d\rho_{ij}(t)}{dt}_{\text{Coll}} = \frac{d\rho_{ij}(t)}{dt}_{\text{Secular}} - d \sum_{ij} \rho_{ij} P_{ij}(t), \quad (6)$$

where the first term on the right-hand side is given by Eq. (4).

The required relaxation matrix elements for Eq. (6) have been constructed using the IOSA, as explained in the Supplementary Note 3 where the consistency with the rates used previously within the secular approximation\textsuperscript{21–23} is demonstrated. Unfortunately, due to computer-time and computer-memory limitations, nonsecular calculations at room temperature, which require to include N₂O \(J\) values up to \(J_{\text{Max}} = 60\), were not tractable (which is not the case when the secular approximation is used). Hence, we carried calculations for \(T = 100\) K and \(J_{\text{Max}} = 38\), conditions for which predictions for 6 densities and 21 delays \(\tau_{ij}\) could be completed in a “reasonable” time. The results of this exercise, in which we used rates computed at 295 K but initial populations defined at 100 K, are displayed in Fig. 3 with a red dashed line. Note that comparing the secular results at 100 K and 300 K shows that limiting computations to \(T = 100\) K and \(J_{\text{Max}} = 38\) only slightly affects the prediction (by 10%). Figure 3 confirms that the nonsecular terms (within the sum on the right-hand side of Eq. (6)), which describe the transfers among coherences as well as...
between populations and coherences, globally contribute to reduce the pressure-induced echo decay at short times. Analysis shows that this result from the fact that these contributions here systematically reduce the collision-induced decay of the amplitudes of the $\rho_{JM J' M'}(t)$ coherences, as exemplified in Fig. 4b, c, and thus also of the echo. In particular, for $N_2O$ diluted in He, the IOS model predicts that, immediately after the first pulse, nonsecular couplings between coherences reduce the collisional damping of these amplitudes by a factor of about two with respect to the secular behavior. Neglecting the nonsecular terms thus leads to overestimate the decay of the system. Note that a similar damping of these amplitudes by a factor of about two with respect to secular couplings between coherences reduce the collisional IOS model predicts that, immediately after the first pulse, nonsecular couplings between coherences, globally contribute to relax the pressure-induced echo decay at short times. Analysis between populations and coherences, globally contribute to reduce the pressure-induced echo decay at short times. Analysis shows that this result from the fact that these contributions here systematically reduce the collision-induced decay of the amplitudes of the $\rho_{JM J' M'}(t)$ coherences, as exemplified in Fig. 4b, c, and thus also of the echo. In particular, for $N_2O$ diluted in He, the IOS model predicts that, immediately after the first pulse, nonsecular couplings between coherences reduce the collisional damping of these amplitudes by a factor of about two with respect to the secular behavior. Neglecting the nonsecular terms thus leads to overestimate the decay of the system. Computations. The density matrix $\rho$ was initialized, before the first laser pulse, to its equilibrium value at 100 and 295 K (see text). Its evolution with time was then obtained by solving Eqs. (1) and (2) for a 100 fs Gaussian pulse envelope (FWHM) and the same pulses intensities as in the experiments, using the anisotropic polarizability $\alpha_{ij} = 19.8 a_0^3$ and the rotational constant $B = 0.419$ cm$^{-1}$ of $N_2O$. The collisional term was computed using Eq. (3), with rates $A_{\alpha\beta}$, which were constructed as explained in the Supplementary Note 3. Considering that all the operators are diagonal in $M$, only the $\langle M|\rho(t)|M'\rangle$ terms were computed. From knowledge of these density matrix elements, the alignment factor was computed from

$$
\langle \cos^2\theta \rangle = \frac{1}{2} \left[ 1 + \frac{M}{3} \right]
$$

with $\langle M\rangle = \frac{1}{2} \sum |M| \rho(M|M)$, where $(|M\rangle \langle M|)$ is a 3 J symbol. Note that this implies $\langle \cos^2\theta \rangle = 1/2$.

Data analysis. For each delay $\tau_2$, between the laser pulses $P_1$ and $P_2$, the measured and computed time-dependent alignment factors for various gas densities were analyzed as follows. The variation with $d$ of the peak-to-dip density-normalized amplitude $S$ of the echo (see Fig. 2b) was (nicely, see Fig. 2c) least-squares fitted by $S(d, \tau_2) = A(t_2) \exp(-d/d_0(t_2))$ floating $A(t_2)$ and $d_0(t_2)$. A density-normalized decay time constant was then defined as $\tau_{12} = 2\tau_2d_0(t_2)$ considering the fact that the echo appears at $t = 2\tau_2$ after the time origin defined by $P_1$. For the revivals, the same approach was used except that $P_2$ was turned off, and a density-normalized time constant was determined for each of them from the decay of their amplitude with density using $\tau_{2} = t_2d_0(t_2)$, where $t_2$ is the time delay between the revival and $P_1$.

Data availability

The measured and simulated data that support the findings of this study are available on reasonable request from O. Faucher and J.-M. Hartmann, respectively.
