Abstract Understanding the anatomy of the ankle ligaments is important for correct diagnosis and treatment. Ankle ligament injury is the most frequent cause of acute ankle pain. Chronic ankle pain often finds its cause in laxity of one of the ankle ligaments. In this pictorial essay, the ligaments around the ankle are grouped, depending on their anatomic orientation, and each of the ankle ligaments is discussed in detail.

Keywords Ankle anatomy · Lateral collateral ligament · Medial collateral ligament · Ankle impingement · Ankle sprain

Introduction

Despite the fact that the ankle ligaments are prone to injury during the fast majority of sports, literature focusing on the ankle ligaments is rare. Proper anatomic knowledge of the different ligaments is important for a correct diagnosis and subsequent treatment.

The most common mechanism of injury to the ankle ligaments is inversion of the foot [4, 33]. With this mechanism of injury, the anterior talofibular ligament is the first or only ligament to sustain injury [43]. A total rupture involves the calcaneofibular ligament and the posterior talofibular ligaments as well [9]. An eversion injury will
cause damage to the deltoid ligaments [3], while a hyper-dorsiflexion trauma might cause an injury to the syndesmotic ligaments [11].

The ligaments around the ankle can be divided, depending on their anatomic position, into three groups: the lateral ligaments, the deltoid ligament on the medial side, and the ligaments of the tibiofibular syndesmosis that join the distal epiphyses of the bones of the leg (tibia and fibula).

In this review article, these three groups of ligaments are described separately, and in each section, the specific ligaments are described in detail.

**The lateral and medial collateral ligaments**

The lateral collateral ligament complex (LCL) consists of the anterior talofibular, the calcaneofibular, and the posterior talofibular ligaments. The medial collateral ligaments (MCL), also known as the deltoid ligament, are a multifascicular group of ligaments and can roughly be divided into a superficial and deep group of fibers [8, 24, 28, 36].
Lateral collateral ligaments

Anterior talofibular ligament

The anterior talofibular ligament is the most frequently injured ligament of the ankle and is the most frequently observed injury in the emergency room [7] (Fig. 1). This ligament plays an important role in limiting anterior displacement of the talus and plantar flexion of the ankle [40].

This ligament is closely related to the ankle joint capsule and is typically composed of two separate bands [23] (Fig. 2). The bands are separated by vascular branches from the perforating peroneal artery and its anastomosis with the lateral malleolar artery. In literature, numerous anatomic descriptions have been given, varying from a single up to three bands [9, 10, 12, 23, 24]; however, in our observation during ankle dissections, this ligament most commonly compromises a double-banded morphology, similar to the description by Sarrafian [36].

The anterior talofibular ligament originates at the anterior margin of the lateral malleolus. The center is on average 10 mm proximal to the tip of the fibula as measured along the axis of the fibula [10]. The overall width (6–10 mm) of the anterior tibiotalar ligament does not appear to vary greatly irrespective of the number of bands present, suggesting that the variations observed do not modify the ligament’s function [40] (Figs. 3, 4).

In plantar flexion, the lower band of the ligament remains relaxed while the upper band becomes taut. In dorsiflexion, the upper band remains relaxed, and the lower band becomes tight.
Calcaneofibular ligament

The calcaneofibular ligament originates from the anterior part of the lateral malleolus. It is anatomically positioned just below the lower band of the anterior talofibular ligament. Frequently, fibers connecting these ligaments can be observed (Fig. 3). In the neutral ankle position, the ligament runs obliquely downwards and backwards to attach to the posterior region of the lateral calcaneal surface (Fig. 5). This ligament is superficially crossed by the peroneal tendons and sheaths, which can leave a concavity over the ligament; only about 1 cm of the ligament is uncovered (Fig. 6).

The anatomic variants of the calcaneofibular ligament and their relationship with the lateral talocalcaneal ligament have been the subject of study [39]. In 35% of the cases, the calcaneofibular ligament is reinforced by the lateral talocalcaneal ligament, attached by the former but diverging proximally or distally. In 23% of the cases, a lateral talocalcaneal ligament exists anteriorly and independent of the calcaneofibular ligament. In 42% of the cases, the lateral talocalcaneal is absent and is replaced by an anterior talocalcaneal ligament. In these cases, the calcaneofibular ligament acquires more functional significance in providing stability to the subtalar joint [39] (Fig. 7).

In cross-section, the ligament is rounded and has a diameter of 6–8 mm, and its length is about 20 mm. This ligament is separate from the ankle joint capsule, but it is intimately associated with the posteromedial part of the peroneal tendons sheath, covering almost the entire ligament [36].

The calcaneofibular ligament is the only ligament bridging both the talocrural joint and subtalar joint. Insertion of this ligament and its axis of rotation point allow flexion and extension movements of the talocrural joint. Depending on its bi-articular characteristic, this ligament also permits subtalar movement.

Broström found that combined ruptures of the anterior talofibular and the calcaneofibular ligaments occurred in 20% of cases and that isolated rupture of the calcaneofibular ligament was very rare [9]. The posterior talofibular ligament is usually not injured unless there is a frank dislocation of the ankle.

Variants in its orientation of the calcaneofibular ligament were studied by Ruth [35]. The calcaneofibular ligament becomes horizontal during extension and vertical in flexion, remaining tense throughout its entire arc of motion (Fig. 5). A valgus or varus position of the talus considerably changes the angle formed by the ligament and the longitudinal axis of the fibula. The ligament is relaxed in the valgus position and tense in the varus position. This explains the potential for injury even without dorsiflexion-plantar flexion movement in the ankle.

Posterior talofibular ligament

The posterior talofibular ligament originates from the malleolar fossa, located on the medial surface of the lateral malleolus, coursing almost horizontally to insert in the posterolateral talus. In plantar flexion and in the neutral ankle position, the ligament is relaxed, while in dorsiflexion, the ligament is tensed. Due to the multifascicular aspect of this ligament, it inserts not just in a specific area. Fibers insert in the posterior surface of the talus, in the peroneal tendons sheath, covering almost the entire ligament [36].
lateral talar process or os trigonum, if present. Some fibers can contribute in forming the tunnel for the flexor hallucis longus tendon (Fig. 8).

Moreover, a group of fibers fuse with the posterior intermalleolar ligament [29]. The posterior intermalleolar ligament has been the subject of recent studies because of its involvement in the posterior soft tissue impingement syndrome of the ankle [17, 27]. Its prevalence of occurrence both in radiological and in anatomic studies vary widely, ranging from 19% up to 100% [24, 27, 30]. In our dissections, the intermalleolar ligament is a consistent finding [16].

In the recent study of Oh et al. [27] on the morphology of the posterior intermalleolar ligament and its correlation with MR images, the posterior intermalleolar ligament was observed in 81.8% of the specimens (63 of 77 specimens). In MRI study, the intermalleolar ligament was identified in all ankles (26 specimens) (Figs. 9, 10).

These differences can probably be explained by its limited size and therefore difficult assessment during an ankle dissection, although Oh et al. [27] propose the number of specimens used or interracial variations. In addition, the ligament may be divided into two or three different bands (20% [34]–100% [27]).

In the posterior view, the posterior intermalleolar ligament is situated between the transverse ligament and the posterior talofibular ligament and runs obliquely from lateral to medial and from downwards to upwards. The shape of the posterior intermalleolar ligament is variable. These variations depend on its medial arising sites, the number of composing fiber bundles, and the degree of the bundle compactness. The medial arising sites of the ligament included the lateral border of the medial malleolar sulcus, the medial border of the medial malleolar sulcus through the septum between the flexor digitorum longus and posterior tibial tendons, the posterior distal margin of the tibia, and the posterior process of the talus through the joint capsule [27] (Fig. 10). The posterior intermalleolar ligament tenses during dorsiflexion and relaxes during plantar flexion, and therefore, trauma that causes forced dorsiflexion of the ankle can be assumed to produce either injury or rupture of this ligament, or osteochondral avulsion. Plantar flexion would cause it to relax and become susceptible to trapping between the tibia and the talus, leading to impingement (Fig. 11).

Since the introduction of the posterior ankle arthroscopy by van Dijk et al. [44, 45] in 2000, the posterior ankle

**Medial collateral ligament**

The anatomical descriptions of the MCL vary widely in the literature; however, in general most agree that it is composed of two layers; the superficial and deep [8, 24, 28, 36].

Similar to the posterior talofibular ligament, the MCL is a multifascicular ligament, originating from the medial malleolus to insert in the talus, calcaneus, and navicular bone.

The tendon sheath of the posterior tibial muscle covers the posterior and middle part of the deltoid ligament in much the same way as the peroneal tendon sheath is associated with the calcaneofibular ligament on the lateral side.

The most commonly accepted description of the MCL is the one originally proposed by Milner and Soames [24]. Six bands or components have been described for the MCL: three of them are always present (the tibiospring ligament, tibionavicular ligament, and deep posterior tibiotalar ligament), whereas the presence of the other three may vary (superficial posterior tibiotalar ligament, tibiocalcaneal ligament, and deep anterior tibiotalar ligament) [8, 24] (Table 1; Figs. 12, 13). Most of the MCL is covered by tendons as it extends down the leg to the bony insertions in the foot (Fig. 14).

Although the description proposed by Milner and Soames has been accepted [24], the anatomy of this ligament and its components is still confusing. During our dissections, we found it rather difficult to determine each individual band, since most are continuous to one another, and therefore pointing out individual bands is artificial.

**Ligaments that join the distal epiphyses of the tibia and fibula**

The talocrural joint consists of a fork-shaped dome formed by the distal tibia and fibula and the talar trochlea enclosed by this mortise. Cartilagenous areas of the ankle joint are not congruent in their surface outlines. In the frontal plane, the talar dome has a slightly concave profile. The planes of the tibial and fibular facets are not parallel. The trochlea is wider anteriorly than posteriorly, and the cartilage covered surfaces have slightly curved sides. The fibular facet has a convex contour, whereas the tibial facet is concave [13].

It is a syndesmotic articulation that allows the tibia-fibula as a whole to adapt to the varying width of the upper articular surface of the talus by slight ascending and medial rotation movements of the fibula during extreme dorsiflexion (maximum width) and by inverse movements during plantar flexion (minimum width) [21].

The syndesmotic ligament complex ensures the stability between the distal tibia and the fibula and resists the axial, rotational, and translational forces that attempt to separate the tibia and fibula. The three ligaments responsible are the anterior or anteroinferior tibiobular ligament, the posterior or posteroinferior tibiobular ligament, and the
interosseous tibiofibular ligament. The inferior segment of the interosseous membrane also helps stabilize the tibiofibular syndesmosis. Distal to the insertion site of this ligament, the remaining anterior surface corresponds to the tibiofibular synovial recess of the ankle joint, and at the posterior surface, there is a small bundle of adipose tissue called the fatty synovial fringe (Fig. 15). The synovial fringe lowers or rises during ankle movements, retracting in dorsiflexion to rise and position itself between the tibia and fibula and descending in plantar flexion toward the ankle joint. This structure has been implicated as a cause of chronic pain following ankle sprain in the condition known as anterolateral soft tissue impingement or more specifically, syndesmotic impingement.

Fig. 11 Anatomic view of the posterior intermalleolar ligament (arrows) showing its involvement in the posterior soft tissue impingement of the ankle. From dorsiflexion (a) to plantar flexion (d), to dorsiflexion (f). 1 Superficial component of the posterior tibiofibular ligament; 2 deep component of the posterior tibiofibular ligament or transverse ligament; 3 posterior talofibular ligament; 4 lateral talar process; 5 medial talar process; 6 tunnel for the flexor hallucis longus tendon; 7 deep layer of the medial collateral ligament (deep posterior tibiotalar ligament)

Table 1 Comparison of the nomenclature used for the medial collateral components, as suggested by Sarrafian [36] and Milner and Soames [24]

| Milner and Soames [24]                        | Sarrafian [36]            |

| Superficial tibiotalar ligament (additional band) | Superficial posterior tibiotalar ligament |
| Tibiocalcaneal ligament (additional band)     | Tibiocalcaneal ligament      |
| **Deep layer**                                |                             |
| Deep posterior tibiotalar ligament (major component) | Deep posterior tibiotalar ligament |
| Anterior deep tibiotalar ligament (additional band) | Deep anterior tibiotalar ligament |

Anterior or anteroinferior tibiofibular ligament

The ligament originates in the anterior tubercle of the tibia (5 mm in average above the articular surface [41]), and its fibers extend in a distal and lateral direction to the insertion site in the anterior margin of the lateral malleolus, with increased length of the fibers distally. Upon examination, the ligament is seen to be divided into several fascicles, allowing the perforation branches from the peroneal artery (Figs. 16, 17). The most distal fibers of the ligament at its origin may be confused with those of the anterior talofibular ligament [1, 6, 36].

The most distal fascicle of the anterior tibiofibular ligament appears to be independent from the rest of the
structure (Fig. 16). It is separated by a septum of fibroadipose tissue and may be slightly deeper than the rest of the ligament. Pathology to this fascicle is frequently described as being responsible for anterolateral soft tissue impingement [1, 2, 5, 32]. Excision of this distal fascicle through open or ankle arthroscopic approach frequently resolves the patient’s complaints, whereas the ankle stability is not comprised [6, 25, 26, 31].

Impingement of the distal fascicle of the anterior tibiofibular ligament appears to depend on changes in the ankle mechanics [6]. An injury to the LCL (e.g., anterior talofibular ligament) would increase anteroposterior laxity of the ankle [20]. This, in turn, would result in increased anterior extrusion of the talus and cause the distal fascicle to have greater contact and pressure on the talus [6]. Another factor related to distal fascicle impingement is the level at which the anterior tibiofibular ligament is inserted in the fibula with respect to the joint line. More distal insertion of the ligament could lead to increased contact in the neutral position of the ankle and a higher potential for ligamentous pathology (Fig. 18). Knowledge of this configuration is important to understand the anatomic bases for anterolateral soft tissue impingement, since abrasion between the distal fascicle of the anterior tibiofibular ligament and the talus may lead to pain (Fig. 19).

Our observations in the dissection room have allowed us to identify contact between the distal fascicle and the talus in the neutral position. This finding is frequently observed during ankle arthroscopy, and the surgeon should consider it a normal feature [2]. This fact has been reported by other authors [1, 19, 22, 26, 32], although in cases of anatomic variation or ankle instability, the feature may be pathological. Contact decreases with joint distraction [2], which should be taken into account during arthroscopy. Akseki et al. [2] observed that section of the anterior talofibular ligament does not alter the contact when the ankle is in neutral position, although important changes are observed when the ankle is in movement. Therefore, ankle instability is one direct factor in anterior tibiofibular ligament pathology.

A diagnosis of this type of ligamentous impingement should be considered in patients with chronic pain in the anterolateral area of the ankle following a sprain, with joint stability and a normal radiological appearance [14].

Posterior or posteroinferior tibiofibular ligament

As is frequently observed, also for this rather strong compact syndesmotic ligament, numerous terminologies have been postulated [5], which is particularly evident in the arthroscopic literature [16].

This ligament is basically formed by two independent components, the superficial and deep component (Fig. 20).
The superficial component originates at the posterior edge of the lateral malleolus and directs proximally and medially to insert in the posterior tibial tubercle. This component would be homologous to the anterior tibiofibular ligament. The term posterior or posteroinferior tibiofibular ligament is usually used to refer to the superficial component (Figs. 20, 21).

The deep component is cone shaped and originates in the proximal area of the malleolar fossa to insert in the posterior edge of the tibia. Its insertion is immediately posterior to the cartilaginous covering of the inferior tibial articular surface; the fibers may reach the medial malleolus (Fig. 21). This component is also known as the transverse ligament, forming a true labrum [36] to provide...
talocrural joint stability and to prevent posterior talar translation [37].

Interosseous tibiofibular ligament

The interosseous tibiofibular ligament is a dense mass of short fibers, which, together with adipose tissue and small branching vessels from the peroneal artery, span the tibia to the fibula. It can be considered a distal continuation of the interosseous membrane at the level of the tibiofibular syndesmosis [18, 36, 38]. Some investigators have suggested that the interosseous ligament is mechanically insignificant, whereas others consider it the primary bond between the tibia and fibula. Hoefnagels et al. [18] suggest that the interosseous ligament plays an important role in the stability of the ankle.
Conclusions

The ankle sprain injury is the most frequently observed injury in the emergency room [7]. Up to 40% of individuals with a history of an ankle ligament injury have been found to have residual complaints interfering with daily living [15, 42]. Adequate knowledge of the anatomy of the ankle ligaments provides a foundation for understanding the basic mechanism of injury, diagnosis, and treatment of these ankle sprains.

Soft tissue impingement syndromes of the ankle are usually preceded by an ankle sprain. Depending on the mechanism of injury, a specific ligament and/or ligaments can be injured [43]. Injury to the anterior talofibular ligament is the most common injury following an ankle sprain. Most frequently, it is an isolated injury; however, in approximately 20% of the patients, also the calcaneofibular ligament is injured [9].

An inversion sprain can result in injury to the capsule, lateral or medial collateral ligaments, or tibiofibular ligaments. The added influence of plantar or dorsiflexion on the injury mechanism will mean that the lesion is predominantly anterior or posterior, respectively, and could also lead to injury to other structures such as the posterior intermalleolar ligament, the osteochondral region of the neck of the talus, or the anteroinferior margin of the tibia.

The mechanism of foot eversion is more closely associated with injury to the medial capsular and ligamentous elements, although an inversion sprain can also produce a lesion to these structures. Medial injury is probably more influenced by the rotating component of the subtalar joint to which the capsule and the MCL are subject.

The aim of this pictorial review on the anatomy of the ankle ligaments is to provide a guide to those who are involved in diagnosing and treating ligament injury around the ankle.
