On the Minimal Adversarial Perturbation for Deep Neural Networks with Provable Estimation Error

Fabio Brau, Giulio Rossolini
Alessandro Biondi, Member, IEEE and Giorgio Buttazzo, Fellow, IEEE
Department of Excellence in Robotics and AI, Scuola Superiore Sant’Anna, Pisa, Italy

Abstract—Although Deep Neural Networks (DNNs) have shown incredible performance in perceptive and control tasks, several trustworthy issues are still open. One of the most discussed topics is the existence of adversarial perturbations, which has opened an interesting research line on provable techniques capable of quantifying the robustness of a given input. In this regard, the Euclidean distance of the input from the classification boundary denotes a well-proved robustness assessment as the minimal affordable adversarial perturbation. Unfortunately, computing such a distance is highly complex due the non-convex nature of DNNs. Despite several methods have been proposed to address this issue, to the best of our knowledge, no provable results have been presented to estimate and bound the error committed.

This paper addresses this issue by proposing two lightweight strategies to find the minimal adversarial perturbation. Differently from the state-of-the-art, the proposed approach allows formulating an error estimation theory of the approximate distance with respect to the theoretical one. Finally, a substantial set of experiments is reported to evaluate the performance of the algorithms and support the theoretical findings. The obtained results show that the proposed strategies approximate the theoretical distance for samples close to the classification boundary, leading to provable robustness guarantees against any adversarial attacks.

1 INTRODUCTION

In the last decade, deep neural networks (DNNs) achieved impressive performance on computer vision applications, such as image classification [1] and object detection [2].

Despite their excellent results, all those models are liable to adversarial attacks, defined as input perturbations intentionally designed to be undetectable to humans but causing the model to make a wrong output [3], [4]. Extensive studies have been conducted for improving these attacks through effective techniques that minimize the distance from the original input to make the resulting adversarial input imperceptible to humans.

Finding the closest adversarial example, or in other terms, the minimal perturbation capable of fooling the model, is a notorious hard problem, because it involves the solution of a non-convex optimization problem with highly-irregular constraints, due to the intrinsic nature of DNNs [4]–[7].

Almost all the powerful attacks presented in the literature (e.g., [4]–[10]) rely on the loss function gradient to build optimization methods for crafting those perturbations. In a nutshell, their basic idea is to move the adversarial perturbation towards the direction that mostly increases the loss function, thus increasing the probability of a misclassification.

Although the above methods provide an affordable empirical solution to the minimal perturbation problem, to the best of our records there is no theoretical analysis that estimates and bounds the error committed.

This paper. Inspired by the known strategies that aim at solving the minimal adversarial perturbation problem, this work aims at providing an approximate solution supported by an analytical estimation of the error committed. The motivation behind this work is to leverage the approximate solution and the analytical findings to provide provable statements regarding the trustworthiness of the classification model with respect to a given input.

In the following, we first discuss the minimal adversarial perturbation problem for a binary classifier and then we extend the analysis to a multi-class classifier. To solve the above problem, we propose two new strategies that leverage a root-finding paradigm for computing the distance from the boundary. Differently from the previous work, aimed at solving the minimum perturbation problem, the proposed strategies allow formulating an error estimation theory that quantifies the quality of the computed distance with respect to the theoretical optimum. More specifically, Section 4 provides provable properties about the existence of a tubular neighborhood with radius $\sigma$, where the error between the approximate distance and the minimum distance from the classification boundary can be bounded. Figure 1 better clarifies the latter point by illustrating an example of binary classification. If $x$ is the input vector and $f(x)$ is the classification function learned by the network, our formulation provides an estimation of the radius $\sigma$ from the classification boundary $B = \{ f(x) = 0 \}$ having some regularity property. The regularity is expressed in terms of the first and the
Fig. 1: Illustration of the addressed problem. The blue points are DNN inputs, while the black line \( f(x) = 0 \) is the classification boundary that distinguishes points belonging to the class \(-1 \) \( (f(x) < 0) \) and class \( 1 \) \( (f(x) > 0) \). The dotted line starting from each point is the unknown optimal perturbation, which is orthogonal to the classification boundary. The black arrows represent the gradient directions. Observe that the gradients computed on the points whose distance from the boundary is closer than \( \sigma \) provide a good approximation to the minimal adversarial distance.

second derivatives of the classifier and measures the linearity of the classification boundary.

Section 5 reports an extensive set of experiments carried out to validate the theoretical findings with a list of tests aimed at estimating the distance of an input from the classification boundary. The objective of such tests is to compare the distance computed by the proposed strategies with the approximate minimum distance obtained with a global-search method. Therefore, we validate the theoretical findings and we propose an empirical estimation of \( \sigma \).

Another set of experiments exploits the theoretical findings presented in Section 4 to derive a lower bound on the magnitude of any adversarial perturbation for a given input. Such a lower bound is assessed by generating a set of powerful adversarial attacks and showing that they are not capable of finding adversarial examples of magnitude lower than the estimated distance derived by the proposed line-search methods.

In summary, this paper makes the following contributions:

- It proposes two strategies based on a root-finding algorithm to solve the minimal adversarial perturbation problem close to the classification boundary.
- It presents an analytical estimation of the error committed by solving the minimal adversarial perturbation problem with the above strategies.
- It provides an analytical estimation of the neighborhood in which the previous analysis holds by leveraging a novel coefficient that measures the regularity of the classifier.
- It presents a rich set of experiments to validate the theoretical findings and a practical estimation of the radius \( \sigma \) that is used to deduce a provable robustness against any adversarial attack bounded in magnitude.

The remainder of this paper is organized as follows: Section 2 briefly reviews previous related work and the most effective adversarial perturbation techniques. Section 3 introduces the two strategies to derive an approximate solution of the minimum adversarial perturbation problem. Section 4 provides the theoretical formulation of the error estimation. Section 5 shows the experimental results. Finally, Section 6 states the conclusion and proposes ideas for future works.

2 BACKGROUND AND RELATED WORKS

This section aims at presenting the problem of finding the closest adversarial example for a given input while discussing the most related papers on this topic.

2.1 Challenges in adversarial robustness

The literature related to adversarial robustness is quite vast. The problem of adversarial perturbations for DNNs was first introduced by Biggio et al. [3] and independently by Szegedy et al. [4]. Since then, a large number of works followed for proposing more powerful attacks [5], [6], [8], [9], detection mechanisms [11]–[13], and defense strategies [14]–[16]. Most adversarial attacks use a gradient based approach to craft adversarial perturbations. Although they generate impressive human undetectable adversarial examples, the reliability of the gradient direction is often taken for granted and no bound was ever provided on the error committed, with respect to the minimal theoretical perturbation.

2.2 Minimum adversarial perturbation problem

We consider a neural classifier with \( n \) inputs and \( C \) outputs, where \( C \) is the number of classes that can be recognized. Let \( f : \mathbb{R}^n \rightarrow \mathbb{R}^C \) be a continuous function such that an input \( x \in \mathbb{R}^n \) produces an output \( f(x) \in \mathbb{R}^C \). For a given input \( x \), the predicted class \( \hat{k}(x) \) is defined as the index corresponding to the strictly highest component of \( f(x) \); in formulas \( \hat{k}(x) \) is such that \( \hat{f}_{\hat{k}(x)}(x) > f_k(x) \) for each \( k \neq \hat{k}(x) \). If the maximum component is not unique, that is, \( \hat{f}_{\hat{k}(x)}(x) = \max_{k \neq \hat{k}(x)} f_k(x) \), then we define \( \hat{k}(x) = 0 \) meaning that the classification cannot be trusted.

It is also useful to define \( R_j := \{ x \in \mathbb{R}^n : \hat{k}(x) = j \} \) as the region of the input space corresponding to the class \( j \), and \( B_j \) as the classification boundary for class \( j \) (or the frontier of \( R_j \)).

Let \( x \) be a correctly classified sample with label \( l \). The problem of finding the minimal adversarial perturbation \( \delta^* \), such that \( x + \delta^* \) is the closest adversarial example to \( x \), can be obtained by solving the following minimization problem

\[
\min_{\|\delta\|} \|\delta\| \quad \text{s.t.} \quad \hat{k}(x + \delta) \neq l,
\]

where \( \|\cdot\| \) represents the Euclidean norm and the scalar value \( d(x, l) \) represents the distance between \( x \) and the closest adversarial example \( x + \delta^* \), or, equivalently, the distance of \( x \) from the classification boundary.

Note that, to practically apply the above formulation to computer vision, two additional constraints are required: box-constraint and integer-constraint. The box-constraint ensures that the adversarial example \( x + \delta \) is such that \( 0 \leq x_i + \delta_i \leq 1 \) (assuming images with pixel values normalized in \([0, 1] \)). The integer-constraint ensures that each pixel \( x_i \) perturbed by \( \delta_i \) is encoded into an integer with \( Q \) gray levels (e.g., \( Q = 256 \)), that is, \( Q \cdot (x_i + \delta_i) \in [0, Q - 1] \cap \mathbb{N} \).
Nevertheless, this work focuses on the unconstrained formulation, as done by Moosavi-Dezfooli et al. [5], since it is more compliant for the proposed analytical study. Note that this does not reduce generality, since the solution of MP provides a lower bound of the constrained problem. Therefore, to reduce clutter, unless differently specified, the domain of the perturbation $\delta$ is equal to $\mathbb{R}^m$.

The following paragraphs review relevant state-of-the-art techniques for finding a practical solution of the previous minimum problem. For the sake of clarity, we group them into different categories depending on the approaches followed for solving MP.

### 2.3 Penalty Methods

A well known technique to solve a minimum constrained problem is given by the Penalty Method [17]. For instance, Szegedy et al. [4] and Carlini and Wagner [6] introduced a penalty term $c$ and solved the following minimization problem:

$$
\min_{\delta} \quad c \cdot \|\delta\| + \mathcal{L}(x + \delta, l)
$$

(1)

where the hyper-parameter $c$ is selected through a line search. The rationale of $c$ is to balance the importance of the two terms in the cost function. The second term $\mathcal{L}$ represents a specific loss function that is positive in region $R_l$ and zero in $\cup_{j \neq l} R_j$. Carlini and Wagner analyzed different loss functions finding that $\mathcal{L}(x, l) = (f_j(x) - \max_{j \neq l} f_j(x))^+$ produces the most effective results, where $f^+ = \max(0, f)$.

It is worth observing that in both works [4] and [6], a box constraint is added to achieve an adversarial perturbation that is feasible in the image domain. In particular, Szegedy et al. [4] exploited the L-BFGS-B optimizer [17] to directly solve the minimum problem with the box-constraint $0 \leq x + \delta \leq 1$, while Carlini and Wagner [6] introduced a change of variable to reduce to the solution of an unconstrained problem.

Although both the previous techniques allow crafting accurate perturbations, they turn out to be expensive in terms of memory usage and computational cost. Moreover, they require to repeat the optimization procedure over multiple choices of the penalty $c$, causing a large number of forward and backward network passes, thus resulting in a slow convergence.

### 2.4 Toward Faster Methods

A key contribution towards less expensive solutions of MP was given by the Decoupling Direction and Norm method (DDN) presented by Rony et al. [9] (recently extended by Pintor et al. [18] for different $l_p$ norms), where the authors avoid searching for the best value of the penalty term $c$. Instead, they search for an adversarial example in the Euclidean ball centered in $x$ with radius $c$ by performing some gradient descent steps with the loss function used to train the model and projecting the result on the sphere. Then, depending on whether the solution is an adversarial example, they adjust the radius of the sphere and iterate the procedure.

Another approach, named Augmented Lagrangian Method for Adversarial Attack (ALMA) [19], uses the same paradigm but avoids searching for the best penalty $c$ through a line-search, by exploiting the Lagrangian duality theory [20].

Although both DNN and ALMA outperform the method by Carlini and Wagner in terms of execution time (by making less forwards and backwards passes), they do not provide a theoretical estimation of the goodness of the solution.

### 2.5 Distance Dependent Attacks

Much closer to this paper, DeepFool (DF) [5] is a famous fast method for finding a minimal adversarial perturbation. It leverages the geometrical properties of a specific distance (e.g., $l_2$) to quickly generate accurate solutions for MP.

In short, the method provides an approximate solution of MP by performing an iterative gradient based algorithm with variable step size at each iteration. To be compliant with the terminology used in Section 3, the problem solved by DF can be rewritten by considering the minimal solution of a list of less expensive minimum problems $d(x, l) = \min_{l \neq l} d_j(x)$, where $d_j(x, l)$:

$$
d_j(x, l) = \min_{\delta} \|\delta\|
\quad \text{s.t.} \quad f_l(x + \delta) \leq f_j(x + \delta).
$$

(2)

The main idea consists of building a sequence $x^{(1)}, x^{(2)}, \ldots, x^{(k)}$ that converges to an approximate solution of MP, which lies in the adversarial region $\cup_{l \neq l} R_j$.

Given $x^{(k)}$, let $f_j(x)$ be the first order approximation of $(f_l(x) - f_j(x))$ in $x^{(k)}$. Then, the next element of the sequence $x^{(k+1)}$ is obtained by considering the minimal solution $d_j(x^{(k)}, l)$ of Problem 2 applied to $f_j(x)$ rather than $(f_l - f_j(x))$. Since $f_j$ is an affine function, the problem has an exact solution of the form

$$
x^{(k+1)} = x^{(k)} - \frac{f_j(x^{(k)})}{\|
\nabla f_j(x^{(k)})\|} \|
\nabla f_j(x^{(k)})\|.
$$

(3)

The procedure turns out to reach convergence in $K \approx 3$ steps, resulting in $2CK$ forward and backward passes, if applied to a classifier with $C$ classes. The comparative study reported in [9] empirically shows that the solution is close to the one found by more expensive methods, as Carlini and Wagner. However, it is crucial to point out that, since the iteration is stopped when the adversarial region is reached, there is no guarantee that the procedure provides a solution of MP. Indeed, the procedure just ensures that a feasible perturbation satisfying the constraint $k(x + \delta) = l$, is found. In other words, to the best of our knowledge, there are no theoretical point-wise estimations of the approximation error, but only estimations of the average distance from the classification boundary [21].

### 2.6 This work

Although the reviewed methods can craft accurate adversarial perturbations, they do not provide an estimation of the error committed with respect to the optimal distance.

Differently from the methods described above, this work presents two methods for finding an approximate solution of MP that simplifies a complex global computation by treating it as a root-finding procedure. This allows formulating an error estimation theory that is formally illustrated in Section 4 and validated in Section 5. Moreover, a final test leverages the estimated error for deriving provable robustness guarantees of a given input $x$ against any adversarial attack.
3 Boundary Distance via Root Algorithm

This section illustrates two main strategies that provide an approximate solution to problem MP by reducing it to a minimal root problem. A theoretical analysis for evaluating the approximation error is provided in Section 4.

Both strategies leverage two main observations: (i) the gradient of $f$ suggests the fastest direction to reach the adversarial region; and (ii) due to the objective function, the minimal perturbation lays on the classification boundary. The two considerations above naturally bring to searching the minimal perturbation as the intersection between the classification boundary and the direction of the gradient $\nabla f$.

3.1 The Case of Binary Classifiers

Differently from a multi-class classifier, a binary classifier can be modeled as a scalar function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ that provides a classification based on its sign, i.e., for each $x \in \mathbb{R}^n$, $k(x) = \text{sgn}(f(x))$. Let $x$ be a correctly predicted sample of class $l \in \{1, -1\}$. Due to the objective, the minimal perturbation $\delta^*$ that solves MP is such that the perturbed sample $x + \delta^*$ belongs to the classification boundary of the binary classifier $l$. Can this easily be proved by contradiction by observing that, if $\delta^*$ is a solution of MP, but $\text{sgn}(f(x)) \neq \text{sgn}(f(x + \delta^*)) \neq 0$, then, due to the continuity of $f$, there exists $0 < t < 1$ such that $f(x + t \delta^*) = 0$, which is a contradiction because $\|t \delta^*\| < \|\delta^*\|$.

Based on this observation, we can replace the original problem with the following minimization problem with an equality constraint

$$d(x, l) = \min_\delta \|\delta\| \quad \text{(MP-Eq)}$$

equivalent to a minimum distance problem from set $B$.

It is worth observing that the gradient $\nabla f(p)$ is orthogonal to the boundary $B$ for each $p \in B$, and that, if $x$ is close to the boundary, then $\nabla f(x) \approx \nabla f(p^*)$ (where $p^* = x + \delta^*$) provides the fastest direction to reach the boundary. Hence, it is reasonable to approximate MP-Eq with the following minimal root problem (a formal proof of this is reported in Section 4):

$$t(x, l) = \min_{t \in \mathbb{R}_+} t \quad \text{s.t.} \quad f(x + t \nu(x)) = 0 \quad \text{(RP)}$$

where $\nu = -\frac{\nabla f(x)}{\|\nabla f(x)\|_2}$ represents the direction that best approximates $\nabla f(p^*)$ at the first order.

3.2 Extension to Multi-class Classifiers

The extension of the binary case to a multi-class classifier is not unique. This section presents two different strategies to tackle the problem.

3.2.1 The closest boundary

The Closest Boundary strategy (CB) leverages the idea that the minimum problem related to a classifier with $C$ classes can be reduced to a list of minimum problems for binary classifiers.

In detail, let $x$ be a sample, correctly classified by $f$ with label $l \in \{1, \ldots, C\}$, and let

$$d_j(x, l) = \min_\delta \|\delta\| \quad \text{s.t.} \quad f_j(x + \delta) \leq f_j(x + \delta). \quad (4)$$

Then, we observe that $d(x, l) = \min_{j \neq l} d_j(x, l)$, where $d(x, l)$ solves MP. This can be proved by reformulating the statement with the following inequalities

$$\min_{j \neq l} d_j(x, l) \leq d(x, l) \leq \min_{j \neq l} d_j(x, l).$$

Let $\delta^{(j)}$ be the solution of $d_j(x, l)$. The second inequality is a consequence from the fact that $\delta^{(j)}$ satisfies the constraint of MP and that, by construction, $d(x, l)$ is lower than $\|\delta\|$ for each feasible $\delta$. The first inequality, instead, can be proved by observing that Problem MP is equivalent to

$$d(x, l) = \min_\delta \|\delta\| \quad \text{s.t.} \quad f_i(x + \delta) \leq \max_{j \neq l} f_j(x + \delta). \quad (5)$$

Hence, if $\delta^*$ is the solution of Problem MP and if $j^* = \arg\max_{j \neq l} f_j(x + \delta^*)$, then, by construction, $\delta^*$ satisfies the constraint of Problem 4 for $f_{j^*}$, and so $\min_{j \neq l} d_j(x, l) \leq d(x, l)$. In conclusion, if $t_j(x, l)$ is the solution of RP with $f(x) = f_i(x) - f_j(x)$, then $d(x, l)$ can be approximated by $t(x, l) = \min_{j \neq l} t_j(x, l)$.

More informally, if $B_{j,l} := \{p \in \mathbb{R}^n : f_i(x) = f_j(x)\}$ is the classification boundary of the binary classifier $f_i - f_j$, we can reduce MP to the problem of finding the closest intersection between the boundary $B_{j,l}$ and the straight line passing through $x$ with the direction provided by the gradient of $f$.

A good aspect of this strategy is that it reduces to the solution of a sequence of minimum problems by preserving the regularity of $f$. In fact, it is important to anticipate that the regularity and the differentiability of $f$ has a big impact on the accuracy of the approximation (see Section 4).

For the sake of clarity, the procedure described above is summarized in Algorithm 1, where function zero called at Line 7, is any root finding algorithm for univariate functions that solves RP.

3.2.2 Fast outer boundary

The CB algorithm presented in the previous section can bring to a large computational cost for a classifier $f$ that distinguishes a large number of classes. In fact, if $O_j$ is the amount of forward and backward passes required to compute each $t_j(x, l)$, then the total cost $O$ can be estimated as $\sum_{j \neq l} O_j$. The Fast outer Boundary strategy (FOB) is hence proposed here to contain the computational cost.

The minimum problem MP can be reduced to the minimal root problem RP by considering $L(x, l) = f_j(x) - \max_{j \neq l} f_j(x)$ and observing that $L$ acts like a binary classifier that takes positive values in the region $R_i$ and negative values in the outer region $\cup_{j \neq l} R_j$. Hence, the approximation of $d(x, l)$ can be deduced by solving the minimal root problem obtained by substituting $f$ with $L$ in Problem RP. Observe that, differently from the previous strategy, this one requires the solution of a single minimal root problem. The pseudocode formulation of the FOB strategy can easily be obtained as a variant of Algorithm 1 by replacing $F$ with $L$ and removing the for loop.
This section formally addresses the problem of estimating the positive minimal estimation of the current label is higher than the actual overall minimal estimation $t$. The proposed method provides an upper bound and a coefficient $p$ such that the approximation error is bounded as follows, for each $p \in (\sqrt{2}, 2)$:

$$\frac{1}{\rho} t(x, l) < d(x, l) \leq t(x, l),$$

and we start the bisection in $[0, \tilde{b}]$.

The pseudocode that implements the Closest Boundary strategy is shown in Algorithm 2. Line 20 reduces the amount of forward passes of the model by stopping the inner iteration if the lower bound $t_{curr\_low}$ of the current label is higher than the actual overall minimal estimation $t$.

### 4 Bounding the Distance from the Classification Boundary

This section formally addresses the problem of estimating the Euclidean distance from the classification boundary. The case of a binary classifier is first considered, while multi-class classifiers are addressed later in Section 4.4.
where the first inequality holds for each \( x \) in \( \Omega_{\sigma(\rho)} \). Such an estimate is only valid in a neighborhood of \( B \) depending on the magnitude of \( \rho \). However, the lower \( \rho \) the smaller the tubular neighborhood in which the inequality holds. In other words, the conditions under which the estimation error can be bounded become more and more difficult to be satisfied as the quality of the bound provided by Inequality (8) increases.

Given a distance \( \varepsilon < \sigma(\rho) \), we say that \( f \) is an \( \varepsilon \)-robust classifier with respect to \((x, l)\) if the sample \( x \) does not admit an adversarial perturbation of magnitude lower than \( \varepsilon \), i.e., if for each perturbation \( \delta \) with \( ||\delta|| < \varepsilon \) then \( k(x) = k(x + \delta) \).

Thus, by only computing \( f(x, l) \), it is possible to deduce the robustness of a classifier with respect to a sample \( x \) according to the following rules:

- If \( t(x, l) < \varepsilon \), then the classifier is not \( \varepsilon \)-robust with respect to \((x, l)\).
- If \( t(x, l) > \rho \varepsilon \), then the classifier is \( \varepsilon \)-robust with respect to \((x, l)\).

### 4.1 Preliminaries

Before going deeper in the mathematical aspects, it is necessary to introduce three assumptions on the function \( f \) of the classifier.

**Assumption A.** The function \( f \) is of class \( C^\infty(\mathbb{R}^n) \).

**Assumption B.** The function \( f \) is strictly positive outside some \( B(0, M) \) (the open ball centered in \( 0 \) with radius \( M \)).

**Assumption C.** The gradient \( \nabla f \) is not zero in \( B \) (i.e., \( 0 \) is a regular value of \( f \)).

Although the three assumptions above are not valid in general, they are not restrictive for a neural classifier. In particular, for a feed forward deep neural network with a one-dimensional output, Assumption B is not verified by \( f \). However, being the samples of our interest always in some closed limited set \( K \), we can theoretically substitute \( f \) in the following proofs with another function \( \tilde{f} \) that coincides with \( f \) in the compact set \( K \) and that satisfies Assumption B. More details can be found in Appendix C.

Similarly, Assumptions A and C are not valid in general, but we can assume that, in a practical domain, \( f \) is the quantized representation of another function \( \tilde{f} \) that satisfies the conditions.

Observe that Assumptions A and C ensure that \( B \) is a smooth manifold of dimension \( n - 1 \) (this can be proved by applying the implicit function theorem [22]). Assumption B, instead, ensures that \( B \) is a compact set.

Since \( B \) is a compact set, then the minimum distance problem formulated in Equation (7) admits a solution for each \( x \in \mathbb{R}^n \). Nevertheless, there is no guarantee that for each \( x \in \mathbb{R}^n \) there exists a unique closest point in \( B \). The following result ensures the existence of a unique solution in a tubular neighborhood of \( B \) (refer to [23] for more details).

**Theorem 1 (Unique Projection [23]).** If \( B \subseteq \mathbb{R}^n \) is a compact manifold, then there exists a maximum distance \( \sigma_0 \) such that for each \( x \) in the open tubular neighborhood \( \Omega_{\sigma_0} \) there exists a unique \( \pi(x) \in B \) that solves Equation (7). Moreover, \( d \) is differentiable in the neighborhood, and \( \nabla d(x) = \frac{x - \pi(x)}{||x - \pi(x)||} \) for each \( x \in \Omega_{\sigma_0} \setminus B \).

Following this result, the lemmas below explain in a formal fashion that, close to the classification boundary, the gradient of \( f \) in \( x \) provides a fast direction to reach \( B \).

Observe that this is the main idea behind all the gradient-based attacks and, in particular, DeepFool [5], which exploits the gradient of \( f \) to rapidly reach the adversarial region.

### 4.2 Bounding the estimation error

Let \( B(x, r) \) be the open ball in the Euclidean norm centered in \( x \) with radius \( r \). Furthermore, for each set \( A \subseteq \mathbb{R}^n \), let \( \overline{A} \) be the closure of \( A \), i.e. the smallest closed set containing \( A \).

**Lemma 1.** Let \( \sigma_0 \) be the distance for which Theorem 1 holds. For each \( x \in \Omega_{\sigma_0} \setminus B \), the direction \( x - \pi(x) \) is parallel to \( \nabla f(\pi(x)) \), where \( \pi(x) \) is the unique closest point in \( B \) to \( x \). In particular,

\[
\nabla d(x) = \frac{x - \pi(x)}{||x - \pi(x)||} = \text{sgn}(f(x)) \frac{\nabla f(\pi(x))}{||\nabla f(\pi(x))||}.
\]

**Proof.** By construction, \( \pi(x) \) is the solution of the minimum problem on Eq. (7). Then, by the Necessary Condition Theorem in [17, p. 278], because of Assumption C, there exists \( \lambda^* \in \mathbb{R}^n \) such that \( \nabla L(\pi(x), \lambda^*) = 0 \), where \( L(p, \lambda) = ||x - p|| + \lambda f(p) \). Observe that \( \nabla L(\pi(x), \lambda^*) = 0 \) implies that

\[
\nabla d(x) = \frac{x - \pi(x)}{||x - \pi(x)||} = \lambda^* \nabla f(\pi(x)).
\]

From the above equation, because \( ||\nabla d(x)|| = 1 \), we deduce that \( ||\lambda^*|| = ||\nabla f(\pi(x))|| \). It remains to prove that \( \text{sgn}(\lambda^*) = \text{sgn}(f(x)) \). To prove this statement, we proceed in three steps: (i) we prove that the segment \( p_t \) that connects \( x \) to \( \pi(x) \) is such that \( \text{sgn}(f(p_t)) = \text{sgn}(f(x)) \) for \( t > 0 \); (ii) we show that for \( t \approx 0 \), the sign of \( \text{sgn}(f(p_t)) \) is equal to the sign of \( \nabla f(\pi(x))^T(x - \pi(x)) \); (iii) by leveraging identity Equation (10), we show that the sign of \( \lambda^* \) is equal to the sign of \( \nabla f(\pi(x))^T(x - \pi(x)) \).

Let \( p_t := \pi(x) + t(x - \pi(x)) \) where \( t \in [0, 1] \). Observe that \( \text{sgn}(f(x)) = \text{sgn}(f(p_t)) \) for each \( t \in (0, 1) \). In fact, by contradiction, if there exists \( \tau \) with \( \text{sgn}(f(x)) \neq \text{sgn}(f(p_{\tau})) \), then, by the Bolzano Theorem applied to function \( f \), it would exist a \( \tau_0 \in (0, 1) \) such that \( f(p_{\tau_0}) = 0 \). This would imply that

\[
||x - p_{\tau_0}|| = ||(1 - \tau_0)(x - \pi(x))|| < ||x - \pi(x)||,
\]

which is a contradiction because \( ||x - p_{\tau_0}|| < d(x) \) but \( \pi(x) \) solves Problem 7.

Based on this fact, observe that, since \( f \) is differentiable in \( p_0 \), then

\[
\begin{align*}
\frac{d}{dt}f(p_t) &= f(p_0) + \nabla f(p_0)^T(p_t - p_0) + o(p_t) \\
&= t \nabla f(\pi(x))^T(x - \pi(x)) + o(p_t),
\end{align*}
\]

where \( o(p_t)/t \to 0 \) when \( t \to 0 \), from which we deduce that for small \( t \), \( \text{sgn}(f(p_t)) = \text{sgn}(\nabla f(\pi(x))^T(x - \pi(x))) \).

In conclusion, multiplying each term of Equation (10) by \( \nabla f(\pi(x))^T \), we deduce that the sign of the first term of the equivalence is equal to \( \text{sgn}(\lambda^*) \), which proves the lemma.

The above result can be seen as a particular case of the following lemma. Intuitively, the next lemma shows that the closer the boundary, the sharper the angle between
which is not zero due to Assumption C. By definition of limit, let 
\[ P, \delta, \pi(x) \text{ observed that the angle between } \nabla f(x) \text{ and the optimal direction } \nabla d(x) \text{ can be bounded in a neighborhood of the boundary } B. \]

**Lemma 2 (Angular Constraint).** For each angle bound \( \alpha \in (-\pi, \pi) \), there exists a distance \( \sigma_1(\alpha) \), such that, for all \( x \in \Omega_\sigma(\alpha) \), the following inequality holds
\[
\frac{\nabla f(x)^T \nabla f(\pi(x))}{\|\nabla f(x)\| \|\nabla f(\pi(x))\|} > \cos(\alpha),
\]
where \( \pi(x) \) is the unique projection of Theorem 1.

**Proof.** From Assumption A, we deduce the continuity of \( \nabla f \). From Assumption C and the compactness of \( B \), we deduce that there exists a distance \( \delta \) such that \( \|\nabla f(x)\| \neq 0 \) in \( \Omega_\delta \) (the closure of \( \Omega_\delta \)), and so we deduce that \( \frac{\nabla f(x)}{\|\nabla f(x)\|} \) is uniformly continuous in \( \Omega_\delta \). Hence, for each \( \varepsilon \), there exists a distance \( \sigma_\varepsilon \leq \delta \) such that, for each \( x, y \in \Omega_\delta \) and \( \|x - y\| < \sigma_\varepsilon \), the following inequality holds
\[
\frac{\nabla f(x)^T \nabla f(y)}{\|\nabla f(x)\| \|\nabla f(y)\|} < \varepsilon.
\]
By remembering that \( \|v - w\|^2 = \|v\|^2 + \|w\|^2 - 2v^T w \) for each \( v, w \in \mathbb{R}^n \), we can deduce the following inequality
\[
1 - \frac{1}{2} \varepsilon^2 < \frac{\nabla f(x)^T \nabla f(y)}{\|\nabla f(x)\| \|\nabla f(y)\|}.
\]
In conclusion, by taking \( y = \pi(x) \) and selecting \( \varepsilon = \sqrt{2 - 2 \cos(\alpha)} \), we deduce Equation (11) where \( \sigma_1(\alpha) = \min(\sigma_0, \sigma_\varepsilon) \).

**Corollary 1.** Let \( \beta \in (0, 1) \) and \( \sigma_2(\beta) \) of Lemma 3. Let \( x \in \Omega_{\sigma_2(\beta)} \), \( p \) such that \( d(x) = \|x - p\| \) and \( r = d(x) \), then the hyperplane
\[
R := \left\{ p + v : v^T \nabla f(p) = -\operatorname{sgn}(f(x)) \beta r \|\nabla f(p)\|, v \in \mathbb{R}^n \right\}
\]
is such that
\[
\forall y \in R \cap B(p, r), \quad \operatorname{sgn}(f(y)) = -\operatorname{sgn}(f(x)).
\]

**Proof.** Let us prove the statement for \( f(x) < 0 \) first. The proof can be decomposed in two steps: (i) Prove that \( p_+ := p + r \beta / \|\nabla f(p)\| \in R \text{ and } f(p_+) > 0 \); (ii) Prove that if \( y \in R \cap B(p, r), \text{ then } \operatorname{sgn}(f(p_+)) = \operatorname{sgn}(f(y)) \).

The first statement can be proved by using a procedure similar to the one adopted in Lemma 1. In particular, let \( p_t := p + t \beta r / \|\nabla f(p)\| \) for \( t \in [0, 1] \) be the segment going from \( p \) to \( p_+ \); first, we prove that \( f \) takes positive values for small values of \( t \); and then we prove that \( f \) does not change sign in \( p_+ \).

Since \( f \) is differentiable in \( p_t \), then
\[
f(p_t) = f(p) + T \nabla f(p) (p_t - p) + o(p_t),
\]
and because \( o(p_t)/t \to 0 \), we can deduce that \( \operatorname{sgn}(f(p_t)) = \operatorname{sgn}(r / \|\nabla f(p)\|) = 1 \) for small \( t \). Let us now prove by contradiction that if \( f \) changes sign in \( p_+ \), then Lemma 3 would be not valid in \( p \). If \( f(p_+) \leq 0 \), then there exist \( \tau^* \leq 1 \) such that \( f(p_{\tau^*}) = 0 \). Hence, \( \|p - p_{\tau^*}\| = \|\tau^* r \beta \|\nabla f(p)\| \), from which \( p_{\tau^*} \in B(p, \tau^* r \beta) \). Let us consider the smaller radius \( r^* = \tau^* r \beta \) and observe that \( p_{\tau^*} \notin B(p, r \beta) \). In fact, \( \tau^* r \beta / \|\nabla f(p)\| \|\nabla f(p)\| = 1 \) shows that \( p_{\tau^*} \) lays on the topological border of the set \( \Gamma_r(p) \) (this brings to a contradiction for Lemma 3 being \( p_{\tau^*} \in B \setminus \Gamma_r(p) \)).

Finally, if \( y \in B(p, r) \cap R \), the second statement can be proved by contradiction observing that, if \( f(y) \leq 0 \), then there exists \( p_0 \in R \cap B(p, r) \) for which \( f(p_0) = 0 \). Furthermore, this would implies that \( p_0 \in B(p, r) \) and \( e_0 \notin \Gamma_r(p) \), which brings to a contradiction by Lemma 3.

In conclusion, the case \( f(x) > 0 \) can be deduced by following the steps above, but considering \( p_- := p - t \beta r / \|\nabla f(p)\| \), to prove that \( f(p_-) < 0 \).
Lemma 2 and Lemma 3 are linked by the following intuitive connection. In a geometrical sense, $d(x)$ represents the length of the shortest path needed to reach the boundary, which is obtained by moving from $x$ along $-\nabla d(x)$.

Similarly, let $t(x)$ be the length of the path (if there exists one) required to reach the boundary by following the direction $\nu(x) = -\text{sgn}(f(x))\frac{\nabla f(x)}{\|\nabla f(x)\|}$, in formulas $x + t(x)\nu(x) \in B$. To ensure the existence of such a $t(x)$, we can leverage two conditions. If we admit that $\nu(x)$ is not similar to the optimal one (i.e., we assume a $\alpha \neq 0$ in Lemma 2), then the existence of $t(x)$ would only be guaranteed by an almost straight boundary $B$, which requires a thickness factor close to zero, $\beta \approx 0$.

Vice versa, if we admit a highly irregular boundary (i.e., $\beta \neq 0$), then the existence of $t(x)$ would only be guaranteed by a direction $\nu(x)$ close to the optimal one. This would require $\alpha \approx 0$.

This is the main idea of the following theorem, which, by balancing the two parameters $\alpha$ and $\beta$, ensures: (i) The existence of $t(x)$; and (ii) The estimation of $d(x)$ through $t(x)$ defined in Equation (8). A graphical idea of the proof is depicted in Figure 2.

![Fig. 2: A graphical proof of Theorem 2. Lemma 3 ensures that in $B(p, r)$ the boundary belongs in the green area. Lemma 2 ensures that $\nu(x)$ (in red) lays in the brown area. In conclusion, there exists a solution $T$ of RP, i.e. an intersection between the boundary and the direction provided by the gradient.](image)

**Theorem 2 (Distance Estimation).** For each angle $\alpha \in (-\frac{\pi}{4}, \frac{\pi}{4})$ there exists a maximum distance $\sigma = \min\{\sigma_1(\alpha), \sigma_2(\cos(2\alpha))\}$ such that the error in approximating $d(x)$ with $t(x)$ can be bounded as

$$\forall x \in \Omega_\sigma, \quad d(x) \leq t(x) \leq 2 \cos(\alpha)d(x),$$

where $t(x) \in \mathbb{R}_+$ is the smallest value such that

$$x - t(x)\text{sgn}(f(x)) - \frac{\nabla f(x)}{\|\nabla f(x)\|} \in B.$$

**Proof.** Let $\beta = \cos(2\alpha)$. Let $\sigma_1(\alpha)$ and $\sigma_2(\beta)$ be the maximum distances of Lemmas 2 and 3, respectively, and let $\sigma = \min(\sigma_1(\alpha), \sigma_2(\beta))$. Note that in this way Lemmas 2 and 3 hold for $x \in \Omega_\sigma$.

Let $p = \pi(x) \in B$ the closest projection, $r = \|p - x\| = d(x)$ the minimum distance from the boundary, and let $\varphi(t) = x + t\frac{\nabla f(x)}{\|\nabla f(x)\|}$ be the straight line passing through $x$ with direction $\nabla f(x)$. Observe that, by definition of $\Omega_\sigma$, it holds $r < \sigma$. Without loss of generality, we can assume that $f(x) < 0$.

The proof strategy consists in proving that the straight line $\varphi(t)$ intersects the hyperplane $R_+ := \{p + v : v^T\nabla f(p) = \beta\|\nabla f(p)\|, v \in \mathbb{R}^n\}$ (which is one of the borders of the set $\Gamma_{\nu}(p)$ of Lemma 3) in a point $\varphi(t_*)$, in which $f$ assumes a positive value. This would imply the existence of some point $\varphi(t(x))$ such that $f(\varphi(t(x))) = 0$.

Observe that the intersection between the support of $\varphi$ and $R_+$ is realized for

$$t_* = \frac{\|\nabla f(x)\|}{\nabla f(x)^T\nabla f(p)} \left(\frac{\beta}{\|\nabla f(p)\|} - (x - p)^T\nabla f(p)\right).$$

Moreover, observe that, multiplying each term of Equation (10) in Lemma 1 by $\nabla f(p)^T$, we deduce that $$(x - p)^T\nabla f(p) = -r\|\nabla f(p)\|$$ from which, by substituting in the second term of Equation (17), we deduce that

$$t_* = \frac{\|\nabla f(x)\|}{\nabla f(x)^T\nabla f(p)} \left(1 + \frac{1}{\cos(\alpha)}\right).$$

Note that with $\beta = \cos(2\alpha)$, the intersection $\varphi(t_*)$ is realized inside the closed ball $B(p, r)$ (details can be found in Appendix D.1).

From Lemma 2, $\frac{\|\nabla f(x)\|}{\nabla f(x)^T\nabla f(p)} < \frac{1}{\cos(\alpha)}$, thus by Equation (18) we deduce the right-hand side of the following inequality

$$d(x) \leq t_* < \frac{1 + \beta}{\cos(\alpha)} r = 2 \cos(\alpha)d(x),$$

while the left-hand side is trivial by construction of $d(x)$.

In conclusion, by observing that $x = \varphi(0)$, if we prove that $f(\varphi(0)) < 0 < f(\varphi(t_*))$, we can deduce the existence of $t(x) < t_*$ such that $f(\varphi(t(x))) = 0$, which finally implies Equation (16).

The condition $f(\varphi(0)) < 0$ holds by assumption. Moreover, by construction, $\varphi(t_*) \in R_+$ and so by Corollary 1 $f(\varphi(t_*))$ is strictly positive. Hence the theorem follows. 

### 4.3 A significant lower bound of $\sigma$

This section presents an analysis of the magnitude of the radius of the tubular neighborhood $\Omega_\sigma$ in which Equation (16) holds and provides a lower bound of the largest $\sigma$.

In particular, the following lemmas provide an analytical estimation of two lower bounds $\sigma_1$ and $\sigma_2$ for $\sigma_1$ and $\sigma_2$, respectively, depending on the gradient of $f$ and on the Hessian $\nabla^2 f$. Henceforth, we make use of the following notation

$$\|\nabla^2 f\| = \max_{x \in K} \|\nabla^2 f(x)\|,$$

where $K$ is a compact set and $\|\nabla^2 f(x)\|$ is the operator norm of the matrix $\nabla^2 f$ induced by the euclidean norm.

**Lemma 4 (Lower bound of $\sigma_1$).** Let $\Omega = \Omega_\sigma$ of Lemma 2. For each $\alpha \in (-\frac{\pi}{4}, \frac{\pi}{4})$

$$\sigma_1(\alpha) := \frac{1}{2} \inf_{x \in \partial \Omega} \frac{\|\nabla f(x)\|}{\|\nabla^2 f\|^{\frac{1}{2}}} (1 - \cos(\alpha)) \leq \sigma_1(\alpha)$$

where $\sigma_1(\alpha)$ is the same of Lemma 2.

**Proof.** See Appendix B.1

\[\square\]
Lemma 5 (Lower bound of \( \sigma_2 \)). For each \( \beta \in (0, 1) \)
\[
\hat{\sigma}_2(\beta) := 2 \beta \cdot \inf_{p \in B} \frac{\|\nabla f(p)\|}{\|\nabla^2 f\|_B} \leq \sigma_2(\beta) 
\]
where \( \sigma_2(\beta) \) is the same of Lemma 3.

Proof. See Appendix B.2.

The lemmas above provide a lower bound \( \hat{\sigma} \) of \( \sigma \) by considering \( \hat{\sigma}(\rho) = \min\{\hat{\sigma}_1(\alpha), \hat{\sigma}_2(\beta)\} \), where \( \alpha \) and \( \beta \) are such that \( \rho = 2 \cos(\alpha) \) and \( \beta = \cos(2\alpha) \).

Therefore, observe that the lower bounds \( \hat{\sigma}_1 \) and \( \hat{\sigma}_2 \) depend on two main parameters that measure the linearity of the function \( f \). In fact, for an affine function \( f(x) = wx + b \), these bounds diverge to \(+\infty\) due to the Hessian of \( f \) that is zero. This is in line with the properties of an affine classifier \( f \), for which the direction provided by the gradient in each point is parallel to the optimal direction needed to reach the boundary.

Moreover, for a highly irregular function, with many stationary points close to the boundary, the bound \( \hat{\sigma} \) could be close to zero, resulting in an extremely small tubular neighborhood for which the distance estimation fails.

In this section, we are interested in finding a value of \( \rho \) that provides the theoretically larger \( \Omega_{\rho}(\rho) \) for which Inequality (8) holds. In practice, this problem is hard to solve — it would require the complete knowledge of all the stationary points of \( f \). However, the following observation brings to an interesting value \( \rho^* \) that provides a lower bound of the form
\[
0 < \hat{\sigma}_1(\rho^*) \leq \max_{\sqrt{2} < \rho < 2} \hat{\sigma}(\rho) \leq \max_{\sqrt{2} < \rho < 2} \sigma(\rho),
\]
where \( \hat{\sigma}_1(\rho^*) \) represents a lower bound of the largest \( \sigma \) for which Inequality (16) holds.

Observation 1 (Lower bound of largest \( \sigma \)). Let \( \Omega = \Omega_\delta \) of Lemma 2, and let \( \alpha^* \) solving \( \frac{1}{2}(1 - \cos(\alpha^*)) = 2 \cos(2\alpha^*) \). Then \( \rho^* = 2 \cos(\alpha^*) \) satisfies Equation (22).

Proof. Let \( \Omega = \Omega_\delta \) of Lemma 2, let \( \sigma_1, \sigma_2 \) those in Lemmas 4, 5, and let \( \hat{\sigma}(\rho) = \min\{\hat{\sigma}_1(\alpha), \hat{\sigma}_2(\beta)\} \), where \( \alpha \) and \( \beta \) are such that \( \rho = 2 \cos(\alpha) \) and \( \beta = \cos(2\alpha) \). Observe that, since \( B \subseteq \Omega_\delta \), then \( \inf_{x \in B} \|\nabla f(x)\| \leq \inf_{x \in \Omega} \|\nabla f(x)\| \) and \( \|\nabla^2 f\|_{\Omega_\delta} \geq \|\nabla^2 f\|_B \). Hence, we can consider the following lower bound of \( \hat{\sigma}(\rho) \)
\[
\inf_{x \in \Omega} \frac{\|\nabla f(x)\|}{\|\nabla^2 f\|_{\Omega_\delta}} \min \left( \frac{1}{2} (1 - \cos(\alpha)), 2 \cos(2\alpha) \right),
\]
where \( \rho = 2 \cos(\alpha) \). And since function \( u(\alpha) := \min\{\frac{1}{2}(1 - \cos(\alpha)), 2 \cos(2\alpha)\} \) has maximum in \( \alpha^* \), the statement follows.

In summary, the above results show that, given a neighborhood \( \Omega = \Omega_\delta \) in which Equation (7) has unique solution (see Theorem 1) and there are no stationary points of classifier \( f \) (see Lemma 2), Inequality (8) holds for \( \rho^* \approx 1.461 \), and \( \sigma^* := \sigma_1(\rho^*) \) is given by the observation above.

4.4 Error estimation for multi-class classifiers

The analysis above can be extended to a multi-class classifier by leveraging the two strategies presented in Section 3. In fact, if \( f : \mathbb{R}^n \rightarrow \mathbb{R}^c \) is a classifier with \( C \) classes, both strategies reduce to a search for a solution of the minimal root problem \( \text{RP} \) for one or more binary classifiers in which the analysis above can be applied.

The Fast-Outer-Boundary strategy presented in Section 3.2.2 consists in solving Problem \( \text{RP} \) for a binary classifier of the form \( L^{(i)} : \mathbb{R}^n \rightarrow \mathbb{R} \) where \( L^{(i)}(x) := L(x, l) = f_i(x) - \max_{x \neq l} f_j(x) \). Thus, by applying Theorem 2 to \( L^{(i)} \), we deduce the existence of a \( \sigma(\rho) \) such that the estimation holds for each sample \( x \) with \( \delta(x) = l \). Therefore, by considering \( \sigma(\rho) = \min \sigma^{(i)}(\rho) \), we obtain the same extension of Equation (8).

The Closest-Boundary strategy presented in Section 3.2.1 consists instead in solving Problem \( \text{RP} \) for a list of minimal root problems relative to binary classifiers of the form \( f_{jl} = f_i - f_j \). In particular, for each \( \rho \), Theorem 2 ensures the existence of a neighborhood with radius \( \sigma_{jl}(\rho) \) such that the following inequalities holds
\[
\frac{1}{\rho} t_j(x, l) \leq d_j(x, l) \leq t_j(x, l), \forall j,
\]
where we keep the notation of Section 3.2.1. By taking the minimum over \( j \neq l \) we deduce the estimation in Equation (8) for every \( x \) with \( \delta(x) = l \) and \( x \in \Omega_{\rho}(\rho) \), where \( \sigma(x) = \min_{j \neq l} \sigma_{jl}(\rho) \). In conclusion, by considering \( \sigma(\rho) = \min_{i,j \neq l} \sigma_{jl}(\rho) \), we deduce an extension of the desired inequality for the multi-class case.

5 Experiments

This section presents a set of experiments aimed at validating the strategies proposed in Section 3. They are executed on four neural classifiers, each trained on a different dataset.

The approximate distances provided by the tested strategies are compared in Section 5.3 with the Iterative Penalty method (Section 5.1), which provides the ground-truth distance. Section 5.4 reports an empirical estimation of \( \sigma \) for three noticeable values of \( \rho \). Finally, Section 5.5 discusses the case in which all the classifiers are attacked with different known methods. The magnitude of each attack is bounded to be lower than \( t(x)/\rho^* \) in order to show that the attack success rate drops to zero for samples in \( \Omega_{\rho^*} \), where \( \delta^* \) is an estimation of \( \sigma^* \).

5.1 Ground Truth Distance Estimation

In order to compare the approximate distances that solve Equation (RP), we need an accurate measure of the theoretical distance \( d(x) \). To tackle this problem, based on the ideas presented in [24] and [6], we solve Equation (MP) by reducing to the following minimum problem with penalty analogous to Equation (1)
\[
d(x, l; c) = \min_{\delta \in \mathbb{R}^n} \|\delta\| + c \cdot L(x + \delta, l)^+
\]
where \( L(x, l) = f_i(x) - \max_{x \neq l} f_j(x) \) and \( L^+ = \max\{0, L\} \).

For each sample \( (x, l) \) and for each penalty value \( c \), we perform a gradient descent with the Adam optimizer [25], with default parameters, up to \( 10^5 \) iterations, stopping the
were evaluated on different datasets, each associated with a whole procedure is implemented in batch mode to exploit As done by Carlini and Wagner [26], the proposed techniques. This dataset contains 60,000 RGB images of size 128 × 128, grouped in 10 classes. It was used to train a vanilla LeNet [28], a compact network similar to LeNet that classifies pixel-wise standardized 48 × 48 images. The training was performed over the first chunk of the dataset, containing about 39,000 images with a data augmentation technique. During training, each image was randomly rotated by an angle in ±5°, translated towards a random direction with magnitude lower than 10%, and finally scaled with a factor between 0.9 and 1.1. Each transformed image was then scaled to have a dimension of 48 pixels per side. The model was trained to minimize the Cross Entropy loss by the SGD optimizer with a learning rate of 7e−3, a momentum of 0.8, and a weight decay of 1e−5, for 100 epochs. The learning rate was decreased every 10 epochs with a multiplicative factor of 0.9. We achieved a 1.2% error rate over the test set, which is comparable with the state-of-the-art classification performance with this dataset.

### 5.3 Comparing distances

This section focuses on comparing the estimated distances to the ground-truth distance for the four network models and corresponding data sets. For each sample \((x,l)\), the approximate distances \(t(x,l)\) are obtained by applying the zero finding algorithms (Bisection and Newton) to the strategies CB and FOB presented in Section 3. The ground-truth distance \(d(x,l)\) is computed through the Iterative Penalty technique presented in Section 5.1.

Figure 3 shows a comparison between the approximate distance \(t(x)\), computed by the Bisection CB strategy, and the ground-truth distance \(d(x)\) for the four models considered in Section 5.2. For each sample \(x\) of label \(l\), each dot in a graph represents the pair \((d(x,l), t(x,l))\). The dashed green line with slope 1 represents the points in which \(d(x,l) = t(x,l)\).

The other three lines have slopes \(\sqrt{2}, \rho^*\) and 2, respectively (where \(\rho^*\) is defined in Section 4) and represent the estimation of Equation (8) for different values of \(\rho\).

Observe that all the points close to the boundary (i.e., those with a small ground-truth distance to the boundary) are located above the green line and below the others, confirming that the estimation \(t(x) \leq \rho d(x)\) holds.

Table 1 reports the average distances from the boundary for each dataset and for each tested strategy. As one may expect, DeepFool (DF) [5] and Iterative Penalty (IP) provide lower distances with respect to our strategies CB and FOB. However, the distances computed by CB and FOB are

| Strategy     | Algorithm | MNIST | FMNIST | CIFAR10 | GTSRB |
|--------------|-----------|-------|--------|---------|-------|
| FOB          | Bisection | 1.803954 | 0.830559 | 1.087711 | 4.885275 |
| CB           | Bisection | 1.645090 | 0.739743 | 1.093022 | 3.665061 |
| FOB          | Newton    | 1.800629 | 0.813728 | 1.064261 | 3.979418 |
| CB           | Newton    | 1.645083 | 0.739525 | 1.080411 | 3.664718 |
| DF           |           | 1.706957 | 0.548780 | 0.722579 | 3.136562 |
| IP           |           | 1.325458 | 0.419569 | 0.492981 | 2.619886 |

| TABLE 1: Average distance from the boundary for the four datasets obtained with different methods.

### GTSRB

The German Traffic Sign Recognition Benchmark [33] contains about 51,000 traffic signs RGB images of various shapes (from 15 × 15 to 250 × 250), grouped in 43 classes. It was used to train a Micronet [34], a compact network similar to LeNet that classifies pixel-wise standardized 48 × 48 images. The training was performed over the first chunk of the dataset, containing about 51,000 images with a data augmentation technique. During training, each image was randomly rotated by an angle in ±5°, translated towards a random direction with magnitude lower than 10%, and finally scaled with a factor between 0.9 and 1.1. Each transformed image was then scaled to have a dimension of 48 pixels per side. The model was trained to minimize the Cross Entropy loss by the SGD optimizer with a learning rate of 7e−3, a momentum of 0.8, and a weight decay of 1e−5, for 100 epochs. The learning rate was decreased every 10 epochs with a multiplicative factor of 0.9. We achieved a 1.2% error rate over the test set, which is comparable with the state-of-the-art classification performance with this dataset.

\[ \sigma \]

the estimation of \( \sigma \)

MNIST and GTSRB. In particular, for MNIST and GTSRB,

and CIFAR10 have a different behavior with respect to

in the previous section, i.e., by applying Equation (25)

observe that the estimation of \( \hat{\sigma} \)

are represented by the dashed red lines. It is important to

the bounds if \( d \) attack. All graphs show that the higher \( d \), the higher the number of samples that escapes the bounds (a sample escapes the bounds if \( t(x,l)/\rho^* \) is higher than real distance from the boundary).

The result of this experiment for the four datasets are shown in Figure 5, in which each graph reports the number of adversarial examples found with magnitude \( t(x,l)/\rho^* \) as a function of the ground-truth distance \( d(x,l) \). In detail, each stepped line reports, as a function of \( d \), the cardinality of the set \( \{ (x,l) \in X : \exists \text{Adv} \varepsilon(x,l), d(x,l) < t(x,l)/\rho^* \} \) rescaled to be one for the maximum value of \( d \), i.e., the fraction of points that are out of the bound for the tested attack. All graphs show that the higher \( d \), the higher the number of samples that escapes the bounds (a sample escapes the bounds if \( t(x,l)/\rho^* \) is higher than real distance from the boundary). In each plot, the values of \( \hat{\sigma} \) computed in Table 2 are represented by the dashed red lines. It is important to observe that the estimation of \( \hat{\sigma} \) was deduced as explained in the previous section, i.e., by applying Equation (25) without knowing the results of the attacks in advance.

The result of this test shows that the two datasets FMNIST and CIFAR10 have a different behavior with respect to MNIST and GTSRB. In particular, for MNIST and GTSRB,

the estimation of \( \sigma^* \) is more selective, meaning that the estimation done by Inequality (8) holds for distances slightly larger than \( \hat{\sigma} \). Moreover, for FMNIST and CIFAR10 datasets,

the estimation of \( \sigma^* \) results to be less accurate, and for few samples (1 sample for each dataset) the attacks succeed even if the ground truth distance is lower than \( \hat{\sigma} \), proving that the the estimation in Inequality 8 does not hold in a neighborhood of radius \( \hat{\sigma} \) at least for one example.

In fact, higher values of \( \hat{\sigma} \) represent a worst case to be tested, since there are more samples with a distance lower than \( \hat{\sigma} \).

By using FoolBox [35], we generated adversarial examples for the four datasets with the following techniques: Decoupling Norm Direction (DDN) [9], Deep Fool (DF) [5], Projected Gradient Descent (PGD) [8], Fast Gradient Method (FGM) [35].

For each dataset \( X \), and for each sample \((x,l) \in X\), we considered the clipped output of FoolBox that is guaranteed to have magnitude lower than \( \varepsilon \), i.e., \( \|\tilde{x} - x\| < \varepsilon \).

Observe that in this test the magnitude of the attack \( \varepsilon \) is never computed by using the ground-truth distance \( d(x,l) \), but by setting \( \varepsilon = t(x,l)/\rho^* \).

The results of this experiment for the four datasets are shown in Figure 5, in which each graph reports the number of adversarial examples found with magnitude \( t(x,l)/\rho^* \) as a function of the ground-truth distance \( d(x,l) \). In detail, each stepped line reports, as a function of \( d \), the cardinality of the set \( \{ (x,l) \in X : \exists \text{Adv} \varepsilon(x,l), d(x,l) < t(x,l)/\rho^* \} \) rescaled to be one for the maximum value of \( d \), i.e., the fraction of points that are out of the bound for the tested attack. All graphs show that the higher \( d \), the higher the number of samples that escapes the bounds (a sample escapes the bounds if \( t(x,l)/\rho^* \) is higher than real distance from the boundary). In each plot, the values of \( \hat{\sigma} \) computed in Table 2 are represented by the dashed red lines. It is important to observe that the estimation of \( \hat{\sigma} \) was deduced as explained in the previous section, i.e., by applying Equation (25) without knowing the results of the attacks in advance.

The result of this test shows that the two datasets FMNIST and CIFAR10 have a different behavior with respect to MNIST and GTSRB. In particular, for MNIST and GTSRB,

the estimation of \( \sigma^* \) is more selective, meaning that the estimation done by Inequality (8) holds for distances slightly larger than \( \hat{\sigma} \). Moreover, for FMNIST and CIFAR10 datasets,

the estimation of \( \sigma^* \) results to be less accurate, and for few samples (1 sample for each dataset) the attacks succeed even if the ground truth distance is lower than \( \hat{\sigma} \), proving that the the estimation in Inequality 8 does not hold in a neighborhood of radius \( \hat{\sigma} \) at least for one example.

6 CONCLUSIONS

This paper addressed the problem of computing the minimal adversarial perturbation by presenting a novel strategy based on root-finding algorithms. Differently from the state-of-the-art methods, which focus on finding the minimal adversarial perturbation, we presented an estimation error theory able to provide a method for verifying the robustness of a classifier for a given input close enough to the classification boundary. The approximate distance \( t(x,l) \) of the input to the boundary results to be less computationally expensive than the true distance \( d(x,l) \), enabling an efficient verification of the \( \varepsilon \)-robustness of a classifier in a sample \( x \in \Omega_{\sigma(\rho)} \).

Such theoretical findings have been evaluated through an exhaustive set of experiments. First, we compared the estimated distances to ground-truth distances on four different models and the corresponding data sets. Then, we derived an empirical estimation \( \hat{\sigma} \) of the distance under which the error can be bounded, and finally we leveraged such an estimation to verify the robustness of the classifier for samples having a distance lower than \( \hat{\sigma} \). This was accomplished by testing several adversarial attacks.

The presented results open two research directions to be addressed in a future work.

First, as shown in Section 4.3, the theoretical bound \( \sigma(\rho) \) depends on the first and the second derivatives of the model, which cannot be easily deduced for general DNN classifiers. Moreover, the estimated value \( \hat{\sigma} \) only provides an empirical upper bound of the theoretical \( \sigma \) on a validation set. However, there are no findings on the accuracy of this empirical estimation with respect to the theoretical one.

Second, Table 2 shows that some of the tested models/dataset (e.g., FMNIST and CIFAR10) have a small \( \hat{\sigma} \). Thus, the conditions under which the estimated distances can be bounded are more difficult to be satisfied. Future work should hence focus at leveraging the proposed coefficient \( inf_{x \in \Omega} \| \nabla f(x) \| / \| \nabla f(x) \|_{\rho} \) in order to design more regular models for which the above estimations hold for a larger amount of samples (i.e., for a larger \( \Omega_{\sigma(\rho)} \) while preserving the classification accuracy of the original models.
Fig. 5: Attack success rate cumulative curve for attacks bounded in magnitude less than $t(x)/\rho^*$ obtained with Bisection method and Closest Boundary strategy. The dashed red line represent $\sigma^*$, which approximates $\sigma^*$ of Theorem 2. For MNIST and GTSRB, none of the samples with distance from the boundary less than $\sigma^*$ can be perturbed by the tested bounded attacks, in accordance with the theoretical results. For the FMNIST and the CIFAR10 dataset, instead, the estimation $\hat{\sigma}^*$ results to be less accurate, failing in a tiny portions of the tested samples (1 sample overall).

APPENDIX A

COUNTER EXAMPLE

Observe that the compactness of the manifold is essential in the Theorem 1. The following example shows this fact.

Claim 1 (Counter-example). If $\mathcal{B}$ is not a compact manifold, then the statement of the Theorem 1 is not more valid in general.

Proof. Let $f : \mathbb{R}^2 \to \mathbb{R}$, defined by $f(x,y) = y - \sin(x^2)$. Observe that

$$\nabla f(x,y) = \left(\frac{-2x \cos(x^2)}{1}, 1\right),$$

so that $f$ respects the assumption Assumption A and Assumption C but not Assumption B. The boundary $\mathcal{B}$ intersects the positive $x$-axis in $x_k = \sqrt{k\pi}$. Observing that $|x_k - x_{k+1}| \to 0$ as $k \to \infty$, we deduce that for each $\sigma$, the minimum distance problem 7 has no unique solution in $\Omega_\sigma$.

\[\]

APPENDIX B

PROOF OF $\sigma$ LOWER BOUND

This section contains further details on the proof of the bounds in Lemma 4 and Lemma 5.

B.1 Proof of Lemma 4

For each $\alpha \in \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$,

$$\frac{1}{2} \inf_{x \in \Omega} \frac{\|\nabla f(x)\|}{\|\nabla^2 f\|_F^2} (1 - \cos(\alpha)) \leq \sigma_1(\alpha)$$

(27)

where $\sigma_1(\alpha)$ is the same of Lemma 2.

Proof. Let $p \in \mathcal{B}$ and let $\Omega = \Omega_\delta$ a tubular neighborhood where $\nabla f \neq 0$ and $\Omega \subseteq \Omega_\delta$ of Theorem 1.

Observe that $F_p(x) = \left\langle \nabla f(x), \nabla f(p) \right\rangle \in C^1(B(p, \delta))$ satisfies the hypothesis of Taylor Theorem [36]. In detail

$$\nabla F_p(x) = \left(\frac{\nabla^2 f(x)}{\|\nabla^2 f\|} - \frac{\nabla f(x)\nabla f(x)^T \nabla^2 f(x)}{\|\nabla f(x)\|^3} \right) \nabla f(p)$$

is a continuous vector field in the ball of radius $\delta$, and so for each $x \in B(p, \delta)$

$$F_p(x) = 1 + (x - p)^T R(x)$$

(28)

where

$$|R| \leq \max_{x \in \mathcal{B}} \max_{\mu} |\partial_{\mu} F_p(x)|$$

$$\leq \max_{x \in \mathcal{B}} \left\| \frac{\nabla^2 f(x)}{\|\nabla f(x)\|} - \frac{\nabla f(x)\nabla f(x)^T \nabla^2 f(x)}{\|\nabla f(x)\|^3} \right\|$$

$$\leq \max_{x \in \mathcal{B}} \left\| \frac{\nabla f(x)\nabla f(x)^T \nabla^2 f(x)}{\|\nabla f(x)\|^3} \right\|$$

and where, for a matrix $A \in \mathbb{R}^{n \times n}$, the notation $\|A\|$ represents the operator-norm inducted by the euclidean norm.

Observing that for each $\|v\| = 1, \|Id - vv^T\| \leq 1 + \|vv^T\| \leq 2$, we can reduce the last inequality as follows

$$|R| \leq M := \frac{2\|\nabla^2 f\|_F}{\inf_{x \in \Omega} \|\nabla f(x)\|^3}$$

where $\|\nabla^2 f\|_F := \sup_{x \in \mathcal{B}} \|\nabla^2 f(x)\|$.

Observe that from the Equation (28) we can deduce the following inequality in $B(p, \delta)$

$$1 - \|x - p\|_1 R \leq F_p(x)$$

from which we deduce

$$1 - \|x - p\|_1 M \leq F_p(x)$$

Moreover, $\cos(\alpha) < 1 - \|x - p\|_1 M$ is a sufficient condition to

$$\cos(\alpha) < F_p(x)$$

for each $x \in B(p, \delta)$, from which we deduce

$$\|x - p\|_1 \leq \frac{\inf_{x \in \Omega} \|\nabla f(x)\|}{2\|\nabla^2 f\|_F} (1 - \cos(\alpha)).$$

(29)

Because the right side is an uniform estimation for each $p$, then we deduce the thesis for all the $x \in \Omega_\delta$ and $p = \pi(x)$.

\[\]

B.2 Proof of Lemma 5

For each $\beta \in (0, 1)$

$$2\beta \inf_{p \in \mathcal{B}} \frac{\|\nabla f(p)\|}{\|\nabla^2 f\|_B} \leq \sigma_2(\beta)$$

(30)

where $\sigma_2(\beta)$ is the same of Lemma 3.

Proof. Let $p \in \mathcal{B}$. By applying the Taylor Theorem [36] to the function $f$ centered in $p$, we deduce that

$$0 = (p - q)^T \nabla f(p) + R(q), \quad \forall q \in \mathcal{B}$$

(31)

where

$$|R(q)| \leq \frac{\|p - q\|_2}{2} \max_{x \in \mathcal{B}} \max_{\mu, \nu} |\partial_{\mu, \nu} f(x)|, \quad \forall i, j$$

(32)

Observe that for each $x$ the value $\max_{\mu, \nu} |\partial_{\mu, \nu} f(x)|$ is known as maximum norm of $\nabla^2 f(x)$, in symbols $\|\nabla^2 f(x)\|_{\max}$. Therefore, for each matrix $A \in \mathbb{R}^{n \times n}$, the following property holds

$$\|A\|_{\max} \leq \|A\|.$$ 

Refer to [37, Sec. 2.3.2] for further details.
By substituting the inequality on Equation (31) we can deduce
\[
(p - q)^T \nabla f(p) \leq \frac{1}{2} \|\nabla^2 f\| \|p - q\|^2. \tag{33}
\]
By imposing that
\[
\frac{1}{2} \|\nabla^2 f\| \|p - q\|^2 \leq \beta \|p - q\|^2 \|\nabla f(p)\|
\]
and observing that \(\|\cdot\|_2 \leq \|\cdot\|_1\) we can deduce that, for each \(p \in B\), the following condition
\[
\|p - q\|_2 \leq 2\beta \frac{\|\nabla f(p)\|}{\|\nabla^2 f\|}
\]
is sufficient to ensure the inequality 14 in Lemma 3. By taking the inf over \(B\) on the right side we deduce an uniform lower estimation of \(r_2\).

\[\square\]

**APPENDIX C**

**ASSUMPTION B FOR DEEP NEURAL NETWORKS**

**Lemma 6.** Let \(f : \mathbb{R}^n \to \mathbb{R}\) a \(L\)-Lipschitz function. And let \(g : \mathbb{R}^n \to \mathbb{R}\) a continuous function such that, for each sequence \(\{x(k)\}\) with \(\|x(k)\| \to \infty\), then \(g(x(k)) \to +\infty\). Hence, there exists a radius \(M\) such that \(f + g\) is strictly positive outside \(B(0, M)\), in formulas
\[
\exists M \forall \|x\| \geq M, \quad f(x) + g(x) > 0 \tag{35}
\]

**Proof.** Let us proceed by reductio ad absurdum. Observe that denying Equation (35) is equivalent to assume the existence of a sequence \(\{x(k)\}\) such that \(\|x(k)\| \to +\infty\), and for which \(f(x(k)) + g(x(k)) \leq 0\). The following chain of inequalities hold
\[
\begin{align*}
g(x(k)) + f(x(k)) & \leq 0 \quad \Rightarrow \quad g(x(k)) + f(x(0)) \leq f(x(0)) - f(x(k)) \quad \Rightarrow \quad g(x(k)) + f(x(0)) \leq L\|x(k) - x(0)\| \\
g(x(k)) & \leq f(x(0)) + L\|x(k)\| + L\|x(0)\| \\
g(x(k)) & \leq L\|x(k)\| + f(x(0)) + L.
\end{align*}
\]
Where we only use the Lipschitz property of \(f\) in the third inequality. Because the second term of the last inequality converges to \(L\), we deduce a contradiction with the hypothesis of \(g\).

\[\square\]

Let \(f\) be some one-dimensional-output deep-forward neural network, and let \(K\) the compact set in which our data live. Let assume \(B(0, M_0) \supset K\) the open ball centered in 0 with radius \(M_0\) that contains the compact \(K\). Being \(f\) a Lipschitz function (see [4]), we can apply the lemma above to \(f\) and \(g(x) = \|x\|^2(1 - BK(x))\) where \(BK \in C^\infty\) is a bump function over \(K\), i.e. a smooth function that is constantly 1 in \(K\) and constantly 0 outside \(B(0, M_0)\).

**APPENDIX D**

**DETAILED PROOF STEPS**

**D.1 Intersection \(\varphi(t_*)\) is contained in \(B(p, r)\)**

The following lines prove that \(\alpha \in (-\frac{\pi}{2}, \frac{\pi}{2})\) and \(\beta \leq \cos(2\alpha)\) are sufficient to assume that the intersection \(\varphi(t_*)\) is realized inside the closed ball \(B(p, r)\).

By imposing that \(\|\varphi(t_*) - p\| \leq r\) we deduce the following chain of equivalent inequalities
\[
\begin{align*}
\|\varphi(t_*) - p\| & \leq r \\
\|\varphi(t_*) - p\|^2 & \leq r^2 \\
\|x + t_* f(x)\|^2 & \leq r^2 \\
\|t_* f(x)\|^2 & \leq r^2 \\
\|t_* f(x)\|^2 & \leq r^2 \\
\|t_* f(x)\|^2 & \leq 0 \\
0 & \leq t_*^2 - 2t_* r \|\nabla f(x)\|^2
\end{align*}
\]
where the second to last inequality is directly obtained by Equation (10) in Lemma 1. By definition \(t_* = \frac{\|\nabla f(x)\|}{\|\nabla f(p)\|^2 + (1 + \beta) r}\), thus by substituting it into the latter inequality, we obtain
\[
0 \leq \|\nabla f(x)\| \|\nabla f(p)\|^2 \quad (1 + \beta) r \leq 2r \|\nabla f(p)\|^2 \|\nabla f(x)\|
\]
\[
0 \leq (1 + \beta) \leq 2 \left( \frac{\|\nabla f(p)\|^2 \|\nabla f(x)\|^2}{\|\nabla f(p)\|} \right)^2
\]
\[
-1 \leq \beta \leq 2 \left( \frac{\|\nabla f(p)\|^2 \|\nabla f(x)\|^2}{\|\nabla f(p)\|} \right)^2 - 1.
\]
Observe by Lemma 2 that the following condition implies the latter inequality
\[
\beta \leq 2\cos^2(\alpha) - 1.
\]
Because, by hypothesis, Lemma 3 requires \(\beta > 0\), then we deduce that
\[
2\cos^2(\alpha) - 1 > 0
\]
that holds only for \(\alpha \in (-\frac{\pi}{2}, \frac{\pi}{2})\). In the vary last, observing that \(2\cos^2(\alpha) - 1 = \cos(2\alpha)\), then by following the chain of equivalent inequalities we deduce the desired statement.
