Identification, Characterization, and Pathogenicity of Colletotrichum Species Causing Anthracnose of Peach in Korea

Dae Min Lee, Oliul Hassan and Taehyun Chang

Department of Ecology & Environmental System, College of Ecology & Environmental Sciences, Kyungpook National University, Sangju, Gyeongsangbuk-do, Republic of Korea

ABSTRACT

Peach (Prunus persica L.) is one of the major fruit crops in South Korea, along with apple, persimmon, and Asian pears. Peach anthracnose is a continuing threat to growers and is accountable for enormous economic loss. In July 2018, anthracnose of peach appeared at different peach orchards in Gyeongsangbuk-do region, Korea. The typical anthracnose symptoms (brown, circular, and necrotic lesions) were observed on the fruits. Anthracnose of peach was surveyed in different peach orchards of Gyeongsangbuk-do, and 20 fungal isolates from 19 diseased fruits were collected. Multigene phylogenetic analyses coupled with morphological characteristic analysis approaches were used for identifying the fungal species isolated from diseased fruits. This study confirmed three Colletotrichum species. Based on the results, Colletotrichum siamense are reported for the first time as causal agents of peach anthracnose alongside C. fructicola and C. fioriniae, which has been reported previously. Pathogenicity assays were performed for the three isolates representing all the species identified, and Koch’s postulates on detached healthy peach fruits were verified. All the identified species were pathogenic on peach fruits as the typical anthracnose symptoms were reproduced. Significant variations in the virulence were observed among fungal species on peach fruit.

Colletotrichum; anthracnose; pathogenicity; new record

1. Introduction

Peach (Prunus persica L. Batsch) is economically a very important fruit crop in Korea. Generally, people eat it as a table fruit. In Korea, it is used in different food industries for making jam (Boksoongah jam), jelly (jelly in jelly), tea (Boksoongah hong Chaa), and juice (Kolpeach). Addition of peach fruit could increase the total phenolic content of beer [1]. Peach has medicinal value as it contains polyamines, γ-aminobutyric acid (GABA), proline, and caffeoylquinic acid, a bioactive polyphenol with high antioxidant activity [1,2]. They are considered as the fruit of happiness, riches, honor, and longevity. Since peach is a delicious fruit containing different nutrients and phytochemicals, some studies investigated the quality characteristics and antioxidant potential of beer prepared by the addition of peach. Peach has various health benefits [3,4] and also contains caffeoylquinic acid, a bioactive polyphenol with high antioxidant activity and beneficial effect on human health [5]. Consumption of peach also potentially protects humans from against various chronic diseases by scavenging the reactive oxygen species.

Anthracnose caused by the fungal genus Colletotrichum is a devastating threat for the cultivation of peach worldwide, including South Korea and USA [6,7]. Anthracnose produces sunken lesions with a circular ring on the fruit and results in the loss of yield and fruit quality [6]. Various fungal species belong to the genus Colletotrichum [6,8]. Colletotrichum gloeosporioides and C. acutatum are species complexes and comprise more than 22 and 30 species, respectively [8,9]. Species within a complex share common morphological characteristic, such as conidial shape and size, colony color, and growth rate. Based on morphological characteristics, identification of species within the complex is very difficult. Furthermore, morphological characteristics of fungal species vary with growth media, temperature, light, and host dependence [8]. Some morphological characteristics, particularly colony color, may change or be lost with repeated subculturing [8]. Molecular tools using multiple sequences have become more popular to delineate the Colletotrichum species. The study of morphological characteristics using molecular analysis is a reliable approach for species-level identification of the pathogen [10].
To date, *C. gloeosporioides* and *C. fioriniae* have been identified and reported as causal agents of peach anthracnose in South Korea [7,11,12]. Hu et al. [6] identified *C. acutatum*, *C. truncatum*, *C. siamense*, and *C. fructicola* as causal agents of peach anthracnose using calmodulin (CAL), glyceraldehyde-3-phosphate dehydrogenase (GAPDH), and b-tubulin (TUB2) sequence data. Conversely, Kim and Hong [11] identified *Colletotrichum* species in peach based on morphological characteristics, which is not enough [8,9]. In our previous study, we identified *C. foriniae* and *C. fructicola* using molecular and morphological analysis. There is also a chance of peach infection with diversified *Colletotrichum* species. Many studies have reported that diverse *Colletotrichum* species are responsible for anthracnose of a single host, for example persimmon, Japanese plum, and pear [13–15]. Novel *Colletotrichum* species are continuously being identified by applying advanced identification methods [10,15]. To improve biosecurity and develop peach anthracnose management strategies, accurate diagnosis of responsible *Colletotrichum* species is essential.

The objective of this study was morphological and molecular characterization of *Colletotrichum* species associated with peach anthracnose in Korea and investigation of the virulence of identified *Colletotrichum* species.

2. Materials and methods

2.1. Fungal isolates and sampling

In 2018, 20 *Colletotrichum* isolates were collected from infected peach fruits in commercial orchards of Sangju, Gimcheon, Yechon, Yeongcheon, and Cheongdo, South Korea. Infected fruits (three fruits per orchard) showing typical anthracnose were collected and brought to the laboratory. The fruits were cleaned by washing with tap water. Disease lesions (5 mm × 5 mm size) were disinfested in 1% NaOCl for 1 min, washed twice with sterilized water, and dried with sterilized tissue paper. Disinfested tissue was plated on water agar (WA) and incubated at 25°C in the dark for two days. Newly emerging hyphae from diseased tissue on WA were transferred to a Petri plate containing potato dextrose agar (PDA). Colonies showing typical morphological characteristics of *Colletotrichum* species were purified by hyphal tipping twice one fresh PDA. Fungal colonies (20) were grouped into two based on morphology. Colonies with pink color were placed in first group, and those with whitish gray color were placed in the second group. There were 14 isolates in the former and six in the latter. A sub sample of seven isolates (three from the first group and four from the second group) was selected to confirm species as morphological characteristic of isolates with in group were identical. All collected isolates were preserved in the laboratory on PDA slant at 4°C in the dark.

2.2. Genomic DNA extraction

For extraction of genomic DNA, around 10 g mycelia were collected from an actively growing 4-day-old culture. DNA from each isolate was extracted using a HiGene™ Genomic column type DNA Prep Kit (BIOFACT, Yuseong-Gu, Daejeon, Korea) following the manufacturer’s instructions. The crude DNA (1 μL) was used for PCR amplification of the target region.

2.3. Multigene amplification and sequencing

The following loci were amplified and sequenced: internal transcribed spacers (ITS) and a partial sequence of beta-tubulin (TUB2), calmodulin (CAL), glyceraldehyde-3-phosphate dehydrogenase (GAPDH), actin (ACT), chitin synthase 1 (CHS-1), and the Apn2bulin (TUB2), calmodulin, and the partial mating type (ApMat). Identification of isolates into *C. gloeosporioides* sensu lato (s.l.) was done using six loci (ITS, TUB2, GAPDH, CHS-1, CAL, and ApMat), whereas identification of isolates into *C. acutatum* s.l. was done using four loci (ITS, TUB2, GAPDH, and CHS-1). To amplify ITS, TUB2, GAPDH, CHS-1, CAL, and ApMat gene, primer pairs ITS1 + ITS4 [16], Bt2a + Bt2b [17], GDF + GDR [18], CHS-79F + CHS-345R [19], CL1C + CL2C [8] and AM-F + AM-R [20] were used, respectively. PCR reaction for each gene was run as described by Hassan et al. [13]. The resulting PCR amplicons were purified and then sequenced commercially at Macrogen, Inc. (Seoul, Korea). The consensus sequence of each gene was obtained by assembling forward and reverse sequences with SeqMan (v. 7.1.0.44; DNASTAR, Inc.) and was then deposited in GenBank (Table 1).

2.4. Sequence alignment, concatenation and phylogenetic analysis

For confirming the phylogenetic relationship of current isolates, sequences (respective genes) of ex-type *Colletotrichum* species in *C. gloeosporioides* s.l. and *C. acutatum* s.l. were retrieved from the GenBank database; these were deposited by Weir et al. [8] and Damm et al. [9], respectively. Individual gene sequence data from current isolates and data retrieved from GenBank were aligned with each other using the MUSCLE tool in MEGA 6 [21] and
edited manually. Gaps in aligned sequences were considered as missing data. Each of the resulting multiple gene sequence alignments were concatenated in Mesquite v. 2.75 [22]. Maximum likelihood (ML) and maximum parsimony (MP) phylogenetic analyses were conducted with MEGA v. 6.0 [21] and Bayesian inference (BI) with MrBayes v. 3.2 [23]. For sampling trees and estimating posterior probabilities of the model parameter in BI phylogenetic analysis, Markov chain Monte Carlo (MCMC) sampler was employed as described by Hassan et al. [14]. The resulting 50% majority rule consensus tree was visualized using FigTree v 1.3.1 [24].

2.5. Morphological characterization

Three isolates (ICKb18, ICKb21 and ICKb36) representing one Colletotrichum species each were selected for morphological characterization. Mycelium plugs (5 mm) were transferred to a fresh PDA plate from the actively growing culture. Morphological characteristics of each colony, including color, mycelial growth rate, and conidia and appressorial characteristics, were evaluated after eight days of incubation at 25°C in the dark. Conidial mass from the culture was mounted in sterilized distilled water or lactic acid. The size (lengths and widths) of 30 randomly selected conidia were measured using an Olympus BX43 microscope at 400× magnification. The slide with conidia mounted in water was put in a Petri plate containing moist tissue and incubated at 25°C with a photoperiod of 12–12 h light/dark cycle for seven days. After seven days of incubation, lesion diameter (LD) was measured using the scale ruler. Disease incidence (DI) was estimated in the term percentage of lesion development compared with the total number of points inoculated. Five fruits were tested for each isolate and control.

2.7. Statistical analysis

The data were averaged, and standard deviation was calculated using MS excel. All data related to conidial and appressoria size and lesion diameter are presented as the average. Mean values of lesion diameter were compared through least significant different test in the SAS (SAS Inc., Cary, NC, USA).

3. Results

3.1. Multigene phylogenetic analysis

Seven representative isolates and reference isolates [8,9] were subjected to multilocus phylogenetic analysis. Phylogenetic analysis for four fungal isolates belonging to C. gloeosporioides s.l. were conducted using the combined sequences of ITS, TUB2, GAPDH, CHS-1, and CAL (Figure 1). The final dataset consisted of 37 taxa and 2391 characters (nucleotide positions), including alignment gap (considered as missing data). The fungal species C. boninense was included as the outgroup in this phylogenetic analysis. In Bayesian analysis, 5650 trees were sampled to construct a 50% majority rule consensus tree and calculate the posterior probabilities. The topologies of BI, ML, and MP trees were congruent. The isolates recovered from infected peach fruits were clustered in two clades.

| Species | Isolate | Host | Location in South Korea | GenBank accession number |
|---------|---------|------|-------------------------|-------------------------|
| C. fructicola | ICKb18 | Peach | Sangju | LC516635, LC516649, LC516642, LC516656, LC516663 |
| C. fructicola | ICKb132 | Peach | Cheongdo | LC516636, LC516650, LC516643, LC516657, LC516664 |
| C. Siamense | ICKb21 | Peach | Gimcheon | LC516637, LC516651, LC516644, LC516658, LC516665, LC516667 |
| C. fructicola | ICKb23 | Peach | Sangju | LC516638, LC516652, LC516645, LC516659, LC516666, LC516668 |
| C. Siamense | ICKb31 | Peach | Yechon | LC516639, LC516653, LC516646, LC516660 |
| C. Siamense | ICKb36 | Peach | Sangju | LC516640, LC516654, LC516647, LC516661 |
| C. Siamense | ICKb47 | Peach | Yeongcheon | LC516641, LC516655, LC516648, LC516662 |
in the *C. gloeosporioides* s.l. phylogenetic tree: two isolates formed a clade with the ex-type isolates of *C. fructicola* (ICMP 18581), whereas another two isolates were clustered with the ex-type isolates of *C. siamense* (ICMP 18642). The isolates belonging to *C. siamense* clade were further confirmed by phylogenetic analysis using ApMat gene sequence data (Figure 2).

For phylogenetic analysis of the *C. acutatum* complex, the concatenated sequences of ITS, TUB2, GAPDH, and CHS-1 were used, which comprised 1576 nucleotide positions including alignment gap and 44 taxa. *Colletotrichum pseudoacutatum* (CBS 43677) was included as the outgroup in this phylogenetic analysis. A total of 4991 tree samples were subjected to BI analysis to construct 50% majority rule consensus tree and estimate posterior probability. There was no basic difference in BI, ML, and MP statistical approach of the *C. acutatum* complex, the concatenated sequences of ITS, TUB2, GAPDH, and CHS-1 were used, which comprised 1576 nucleotide positions including alignment gap and 44 taxa. *Colletotrichum pseudoacutatum* (CBS 43677) was included as the outgroup in this phylogenetic analysis. A total of 4991 tree samples were subjected to BI analysis to construct 50% majority rule consensus tree and estimate posterior probability. There was no basic difference in BI, ML, and MP tree topological structures.

Phylogenetic tree (constructed using BI, ML, and MP statistical approach) of the *C. acutatum* complex showed that present isolates were clustered with ex-type isolates of *C. fructicola* CBS 125396 (Figure 3).

### 3.2. Morphological characterization

Distinct morphological characteristics, including colony color and conidial shape, were observed in the isolates of *C. gloeosporioides* s.l. (*C. fructicola* and *C. siamense*) and *C. acutatum* s.l. (*C. fioriniae*). Pinkish colony and fusiform conidia of *C. fioriniae* were easily disguisable from those of *C. fructicola* and *C. siamense* (Figure 4). The conidia of both *C. fructicola* and *C. siamense* isolates were almost similar in terms of conidial shape, including cylindrical and obtuse end; however, they can be distinguished from each other by colony color (Figure 4). The colony color of *C. siamense* isolates was whitish to gray, whereas that of *C. fructicola* was olivaceous with a white margin. The size of the conidia of *C. siamense* isolate was 13.12–20.15 μm × 5.0–7.8 μm (mean ± SD = 17.3 ± 1.5 × 6.2 ± 0.8 μm), *C. fructicola* isolate was 12.8–20. C × 4.4–7.00 μm (mean ± SD = 16.3 ± 1.1 × 5.1 ± 1.0 μm), and *C. fioriniae* isolate was 8.1–15.1 × 4.3–7.0 μm (mean ± SD = 12.1 ± 1.3 × 5.4 ± 0.6 μm) (Table 2). There was little difference among the present isolates (*C. fructicola*, *C. siamense*, and *C. fioriniae*) in terms of appressorial shape and size (Figure 4; Table 2). The size of appressoria of *C. siamense* isolate was 7.1 to 13.2 × 7.1 to 8.9 μm (mean ± SD = 11.0 ± 1.9 × 7.9 ± 1.0 μm), *C. fructicola* isolate was 8.5–12.0 × 6.4–8.3 μm (mean ± SD = 9.2 ± 1.5 × 7.1 ± 0.5 μm), and *C. fioriniae* isolate was 8.5–15.2 × 4.9–9.4 μm (mean ± SD = 12.5 ± 1.5 × 8.2 ± 1.1 μm) (Table 2).

### 3.3. Pathogenicity assay

Three isolates (one from each *Colletotrichum* species) were selected for confirming Koch’s postulates with a spore suspension on detached peach fruits. All *Colletotrichum* species were pathogenic irrespective of the lesion size and % disease incidence under both wounded and unwounded conditions (Table 3). *C. fructicola*, *C. siamense*, and *C. fioriniae* were more virulent under wounded conditions than...
under unwounded conditions. The average DI of each isolate was 100% under wounded condition and 30%–50% under unwounded condition. The average LD of each isolate ranged from 9 mm to 22 mm under wounded condition and 2 to 3 mm under unwounded condition. LD produced by all isolate in unwounded condition were statistically insignificant. The average LD value of *C. fioriniae* was 9.5 mm, which was significantly smaller than that of *C. siamense* or *C. fructicola*. The LD value of *C. siamense* was 18.7 mm and *C. fructicola* was 21.5 mm (Table 3).

4. Discussion

The genus *Colletotrichum* was first introduced to the family *Glomerellaceae* (Glomerellales, Sordariomycetes) by Corda in 1831 [25]. Since then, numerous species have been introduced to this genus. Many species have been introduced, typified, and synonymized through several revisions of the genus *Colletotrichum* in the past decade, and this process is still going on. Species belonging to *Colletotrichum* can be endophytic, parasitic, or saprobic [8,9,26–29]. *Colletotrichum* species are currently identified based on morphological and molecular analyses. Identification of *Colletotrichum* species solely based on morphological characteristics is not reliable and may lead to misidentification [8,26]. Therefore, mycologist recommend using a polyphasic approach, including the analysis of geographical, ecological, morphological, and genetic data to identify the pathogen at the species level [26,27]. DNA sequence data are very crucial to identify species diversity within a genus. Phylogenetic analysis using concatenated sequences of multiple genes is a proven powerful tool for delimitation of species within a genus [26–28].

The main objective of this study was to identify *Colletotrichum* species associated with peach anthracnose using morphological and multi-locus phylogenetic analyses and pathogenicity tests to confirm Koch’s postulates. This study revealed three species belonging to the *C. gloeosporioides* complex (*C. siamense* and *C. fructicola*) and the *C. acutatum* complex (*C. fioriniae*). Among these, *C. siamense* was confirmed to be associated with peach anthracnose for the first time in South Korea. The isolates of *C. siamense* and *C. fructicola* were morphologically typical of *C. gloeosporioides* s.s. (mean species) responsible for peach anthracnose according to Kim and Hong [11]. However, Kim and Hong [11]
identified *C. gloeosporioides* s.s. based on morphological characteristics alone, which cannot unequivocally identify an isolate at the species level. Reportedly, 22 species and one subspecies within *C. gloeosporioides* s.l. (species complex) were micro-morphologically almost similar [8]. Eight gene sequences were used to separate the species within *C. gloeosporioides* s.l. by Weir et al. [8]. In this study, we combined ITS, TUB2, GAPDH, CHS-1, and CAL sequence data for solid identification of isolates from peach to be either *C. siamense* or *C. fructicola*. Many scholars suggested that not all eight gene sequences are required to reliably separate *Colletotrichum* species within *C. gloeosporioides* s.l. [6]. Weir et al. [8] suggested that ITS, TUB2, GAPDH, CHS-1, and CAL gene sequence data are effectively distinguished between *C. siamense* and *C. fructicola*. Hu et al. [6] used concatenated sequences of TUB2, GAPDH, and CAL for clearly identifying *C. siamense* and *C. fructicola* isolates by comparing them against sequences available in GenBank. Another important fact of this study is the use of ApMat gene sequence to confirm *C. siamense* isolates (Figure 2). The sequences of ApMat gene are a powerful tool for the identification of *C. siamense* [8,20]. *C. siamense* was isolated from diseased fruits for the first time. In a previous study, we have described *C. fructicola* as the causal agent of peach anthracnose [30].

Some isolates from peach were also identified as *C. fioriniae*, which belongs to the *C. acutatum* complex (clade 3). The morphological characteristics, including pink colony and fusiform conidia, of present isolates are very typical and similar to those of *C. fioriniae*, as reported by Damm et al. [9]. Thirty-one species have been excepted within the *C. acutatum* complex by Damm et al. [9]. They used concatenated sequences of ITS, ACT, TUB2, CHS-1, GAPDH, and HIS3 for delineating species within the *C. acutatum* complex, whereas, in this study, we used combined sequences of ITS, TUB2, GAPDH, and CHS-1 for identifying *C. fioriniae* isolates. The only representative species of clade 3 which is distinct within the *C. acutatum* complex is *C. fioriniae*,

Figure 3. A 50% majority rule consensus tree obtained by Bayesian inference analysis based on ITS, TUB2, GAPDH, and CHS-1 sequence alignment. Bayesian posterior probability values ≥ 0.5 and bootstrap support values ≥ 50% are shown at the nodes (PP/ML/PM). The used reference was a *Colletotrichum* sp. from within the *Colletotrichum acutatum* species complex obtained from Damm et al. [9]. Species isolated in this study are shown in different color blocks.
and it can be separated using any sequence of ITS, ACT, TUB2, CHS-1, GAPDH, and HIS3 [9]. The isolates of C. fioriniae from peach were easily distinguished from those of the C. gloeosporioides complex (C. siamense and C. fructicola) because of their pinkish colony (Figure 4).

Table 2. Morphological characterization of representative Colletotrichum spp. isolates identified in this study.

| Characteristics | Colletotrichum siamense (ICKb21) | Colletotrichum fructicola (ICKb18) | Colletotrichum fioriniae (ICKb36) |
|-----------------|---------------------------------|-----------------------------------|---------------------------------|
| Colonies        | Cottongy, whitish to gray, fast growing | Cottongy, olivaceous with white margin, fast growing | White to pale olivaceous gray aerial mycelium with a pinkish revers |
| Conidia Shape   | Hyaline, cylindrical with rounded ends | Hyaline, cylindrical with rounded ends | Aseptate, fusiform to cylindrical with both ends acute |
| Size            | 13.12 to 20.15 × 5.0 to 7.8 μm (mean ± SD = 17.3 ± 1.5 × 6.2 ± 0.8 μm) | 12.8–20.2 × 4.4–7.00 μm (Mean ± SD = 16.3 ± 1.1 × 5.1 ± 1.0 μm) | 8.1–15.1 × 4.3–7.00 μm (mean ± SD = 12.1 ± 1.3 × 5.4 ± 0.6 μm) |
| Appressoria Shape | Globose to cylindrical, entire or lobed margin, brown to dark brown | Globose, brown to dark brown | Ellipsoidal sometimes oval, entire edge brown to dark brown |
| Size            | 7.1 to 13.2 × 7.1 to 8.9 μm (mean ± SD = 11.0 ± 1.9 × 7.9 ± 1.0 μm) | 8.5–12.0 × 6.4–8.3 μm (mean ± SD = 9.2 ± 1.5 × 7.1 ± 0.5 μm) | 8.5 to 15.2 × 4.9 to 9.4 μm (mean ± SD = 12.5 ± 1.5 × 8.2 ± 1.1 μm) |

Figure 4. Morphological characteristics of present isolates belonging to different Colletotrichum species. (A–C) A 7-day-old colony on PDA; (D–F) Conidia. G–I. Appressoria.

C. siamense, C. fructicola, and C. fioriniae are believed to have a wide range of hosts [8,9]. In Korea, these three species have been frequently reported as causal agents of anthracnose affecting different fruit crops, such as apple, Japanese plum, and persimmon [13,14,31,32]. Pathogenic C. siamense has
previously been isolated from Diospyros kaki, Malus domestica, and Prunus salicina [13,14,31], C. fructicola from Malus domestica and Prunus salicina [13,14,31,32], and C. fioriniae from Lycium chinense, Prunus salicina, Prunus persica, and Solanum melongena in South Korea [13,14,31,33,34].

The result of the pathogenicity test suggests that all the Colletotrichum species described in this study are virulent on detached peach fruits irrespective of DI and DL (Figure 5). All the three Colletotrichum species were re-isolated from artificially inoculated peach fruits and identified as the same species based on morphological characteristics, thus confirming Koch’s postulates.

In conclusion, this study provides the first morphological, molecular, and pathological characterization of Colletotrichum species in association with peach anthracnose in South Korea. More specifically, this study is also the first report on peach anthracnose caused by C. siamense in South Korea.
