Abstract. The historical seismicity catalogs report that the Gargano area (Apulia region, southern Italy) has been site of medium to high magnitude earthquakes. Instrumental seismicity suffers of the poor coverage of the seismic stations of the RSN (National Seismic Network). To improve the seismological monitoring of the area, in 2013 the OTRIONS seismic network (OSN), managed by the University of Bari - Italy, in cooperation with INGV (National Institute of Geophysics and Volcanology), was installed. In this study, focal mechanisms of single and composite events have been computed using 118 micro-earthquakes occurred in this area. We subdivided the dataset into subsets according to their location and depth, distinguishing between the Promontory zone and the Apulian foredeep. High quality focal mechanisms and low-misfit stress tensor inversion were obtained for three groups of events. To better constrain the stress tensor we included also focal mechanism solutions obtained in previous studies. In the southwestern Apulian foredeep zone, a normal fault kinematics is inferred, normal to the Apennine stress direction; in the Promontory zone, the fault kinematics indicate inverse fault mechanisms striking in NE-SW direction. Differently from previous analyses, the stress orientations inferred in this study agree with those inferred in the World Stress Map.

Keywords: Gargano promontory (Southern Italy) · Focal mechanisms · Stress tensor inversion · Microseismicity · OTRIONS seismic network

1 Introduction

The Apulia region (southern Italy) is presently characterized by low to moderate seismicity, as shown by the instrumental observations, while the historical catalogues report 15 earthquakes with $M_w > 5.5$ striking the Gargano promontory and surrounding area since 1361 (Rovida et al. 2019) (Fig. 1). The historical San Severo earthquake, occurred in 1627, is the most energetic earthquake in the area (Del Gaudio et al. 2007), even if the identification of the causative fault is still an open question. On the contrary, both the recent 2002 San Giuliano di Puglia earthquake and the 1893
Mattinata earthquake are related to the activity along the E-W trending South Gargano fault line (Borre et al. 2003). In fact, it is generally accepted that the Molise earthquake is due to the reactivation of E-W striking faults (Di Bucci and Mazzoli 2003; Valensise et al. 2004) whose surface expression is probably represented by the E-W Mattinata fault (Fig. 1) in the Gargano Promontory (Tondi et al. 2005).

Analyzing 10 years of seismicity (1995–2004), Milano et al. (2005) concluded that the E-W striking fault system in the Gargano Promontory presents a dextral slipping in response to a NW-SE compression, affecting the deeper layers of the crust, since the foci depths concentrate between 15 and 25 km. This behavior is interpreted as a geodynamic process consisting of the eastward rollback of the Adriatic foreland respect to the Apulian foreland that, causing a northeastward propagation of the thrust front of

Fig. 1. Seismicity of northern Apulia extracted in the blue polygonal area from the CPTI2015 version 2.0 catalogue (Rovida et al. 2019). Circles represent focal volumes according to Bath and Duda (1964) formula: thicker ones correspond to events with $M_w \geq 5.5$: blue, green and red ones correspond to events occurred between 1361–1983, 1984–1999, 2000–2017, respectively. Noteworthy fault systems, proposed as possible seismogenic structures by authors cited in brackets, are shown with red lines: A.F. = Apricena fault (Patacca and Scandone, 2004), C.F. F. = Cerignola - Foggia fault (Patacca and Scandone, 2001), M.F. = Mattinata fault (Valensise et al., 2004), S.F. = Sannicandro Garganico - Apricena fault (Salvi et al., 1999), T.F. = Tremiti fault (Favali et al. 1993). The study area is marked by green line. (Color figure online)
Northern Apennines faster than that of Southern Apennines, determines the active
dextral strike-slip tectonics on both the Gargano Promontory (Milano et al. 2005) and
on the Tremiti Islands (Doglioni et al. 1994).

By analyzing the instrumental seismicity occurred between 1985 and 2004, Del
Gaudio et al. (2007) tried to identify the seismogenic structures responsible of both the
1627 San Severo earthquake and the seismicity of the northern Apulia. The authors
distinguished between foreland and foredeep regions: the first one is characterized by a
regional stress combining NW compression and NE extension, so that seismogenic
structures should be strike–slip faults (N-S sinistral or E-W dextral faults), with a slight
transpressive character; the second one is characterized by transtensive mechanisms
with NW oriented normal faults, similar to the dominant NE extension of the Apennine
chain.

In the Gargano area, the local seismic network OTRIONS (hereafter OSN) revealed
an intense seismic activity never recorded before, with magnitude less than that of the
Apennine Chain.

In this paper we propose an evaluation of the stress field regime in the Gargano
promontory, through a focal mechanism analysis of microearthquakes recorded by the
OSN seismic network. We investigate the lateral and depth dependence of the stress
field in the Gargano Promontory fault zone. Since about the 80% of the recorded
earthquakes have magnitude smaller than 2, we carried out a preliminary manual
refined picking of seismograms. Focal mechanisms for both the single and the com-
posite event, were computed from the inversion of P wave polarities. Several tests were
carried out by inverting different combinations of data. Finally, based on the obtained
results and other observational evidence, a possible stress accumulation mechanism of
the Gargano Promontory is proposed.

2 Data from the OTRIONS Seismic Network

The dataset considered in this paper is described by de Lorenzo et al. (2017). It consists
of about 400 earthquakes localized in the Gargano Promontory and surrounding areas,
occurring over a period of approximately 15 months (from April 2013 to July 2014).
The events were recorded mainly by OSN and sporadically integrated by some stations
belonging to the national seismic network of the INGV. Over 93% of the considered
events were not detected by the INGV Earthquakes National Center (CNT). The
maximum epicentral distances do not exceed 25 km and the magnitudes range from 0.1
to 1.7.

The considered earthquakes can be grouped into three categories according to the
depth and geographical position of their hypocenter. Following the work of Filippucci
et al. (2019a), we have analyzed the G1 group of events (blue circles in Fig. 2) among
the events that fall within the area with the greatest surface heat flow density (ZSW area
in Filippucci et al. 2019a), the G3 group of events (red circles in Fig. 2) that fall into
the area with the lowest surface heat flow in the Gargano Promontory (ZNE area in
Filippucci et al. 2019a) and a group of events (G2 group, yellow circles in Fig. 2) which fall into a “transition zone” between the ZSW and ZNE areas.
Group G1. It consists of 38 events located in the area bounded between the Apulian foredeep and the Gargano foreland. The foci depth is rather shallow, between about 1 and 10 km, with an average depth of 3.8 km. The magnitudes are very small, ranging between 0.7 and 1.5 (average magnitude 1.0).

Group G2. It consists of 35 events with epicenters belonging to an area between the shallower (G1 group) and the deeper (G3 group) earthquakes. The foci depth ranges between 10 and 20 km with an average of 16.5 km. The magnitudes vary between 0.1 and 1.6 with an average of 0.8.

Group G3. It consists of 45 earthquakes which occurred inside the Gargano Promontory. The hypocentral depths range between 17 and 28 km, with an average of about 22 km. The magnitudes range between 0.3 and 1.7 (average magnitude 0.9).

The three identified groups of events were then used to derive the fault plane solutions of the Gargano micro-earthquakes as a function of the depth by moving along the SW-NE direction.

3 Single and Composite Fault Plane Solutions

The fault plane solutions were calculated using the FPFIT code (Reasenberg and Oppenheimer 1985). The velocity model used for the computation of the azimuths and the take-off angles is the same as that used for the location of events (de Lorenzo et al. 2017). We examined 118 earthquakes, 966 P-wave were picked, and 648 P-polarities were recognized. We discarded all the events for which less than 6 polarities were available allowing the inference of the fault plane solutions only for 58 micro-earthquakes. The remaining 60 events, characterized by a number of P polarities less than 6, were however used in the determination of the composite focal mechanism.
From the focal mechanism solutions, we selected the solutions based on the two FPFIT output quality factors $Q_f$ and $Q_p$. All focal mechanisms with one or both quality factors C were rejected. Another useful parameter in the FPFIT inversion output is STDR, i.e. the station distribution ratio, that ranges inside \{0.0, 1.0\} and sensitive to the distribution of the data on the focal sphere, relative to the radiation pattern. When STDR < 0.5 it means that a relatively large number of data fall too close to nodal planes; such a solution is less robust than one for which STDR > 0.5 and then it was rejected.

As discussed by Imanishi et al. (2011), P wave first-motion polarity alone cannot constrain the mechanism of earthquakes by using only few data. Since most of the events have magnitude less than 2, the number of P wave polarities ranges between 6 and 12. Although this is a high number of P polarities for events with this small size, it remains a low number for the purpose of constraining the fault plane solution. In order to better constrain to the FPFIT inversion, we attributed a weight to the polarity datum which varies from 0 to 2 (following the weighting of the picking used by SAC software). The attribution of the weights to the polarity data used in the FPFIT inversion lowers the misfit. The best fit solution of each event was determined by minimizing the residual between the observed and theoretical amplitudes, where a grid search approach was applied for strike, dip, and slip angles at 5° intervals. The next step was to obtain the composite focal mechanism for each identified group of events; the use of P polarities of grouped events allows to increase the coverage of the focal sphere under the hypothesis that the events of each group are attributable to an ideal single structure.

Group G1. For this group a total of 149 P-polarities was recognized among 264 identified P-wave arrival times. As concerns the single event solutions, 10 focal mechanism solutions were determined and 9 of them are constrained by data. Following the diagram of Zoback (1992), 3 of the 9 single focal mechanisms are of unknown (U) fault type and were discarded. The remaining 6 fault plane solutions are listed in Table 1 and plotted in Fig. 3 (locations in Appendix).

The composite focal mechanism was then obtained by performing two different inversions: the first by considering the polarity data of all the 38 earthquakes of the group; the second by considering only the 9 best single solutions. The results of the 2 obtained composite focal mechanism are very similar to each other (Table 4) and are classified as normal fault (NF) type (Fig. 3).

Group G2. For this group a total of 214 P-polarities was recognized among 298 P-wave arrival times. As concerns the single event solutions, 20 focal mechanism solutions were determined, with rather stable solutions. Three of these events were discarded because of the quality factors of type C, two events were discarded since STDR < 0.5. As a result of this data selection, 15 single focal mechanism solutions were finally classified as thrust fault (TF) type and one NF type (Table 2 and Fig. 3, locations in Appendix).

The composite focal mechanism, obtained using all the available 214 polarities of the 35 events, is of the TF type and it remains stable also considering only the 15 best solution events (Table 4, Fig. 3).

Group G3. For this group a total of 404 P-polarities was recognized among 285 P-wave arrival times. As concerns the single event solutions, 28 focal mechanisms were determined. After the data selection by the quality factors and the STDR criterion, 13
single focal mechanism solutions were constrained with the majority of the events of TF type and only few solutions classified as strike-slip (SS), NF type and 4 of the U type, which were rejected (Table 3 and Fig. 3, locations in Appendix).

When computing the composite fault plane solutions both using all the available polarities and also limiting the inversion to the best solution events (Table 4), the fault plane solution is quite stable, and classified as TF type (Fig. 3).

Table 1. List of fault plane solutions of the events of group G1. For each event the identification number (Id), strike $\phi_1$, dip $\delta_1$ and rake $\lambda$ of the 2 nodal planes, the trend and plunge of the P and T axes, the STDR, the quality factors ($Q_f$ and $Q_p$) and the fault type (FT) are reported.

| G1 (Id) | $\phi_1$ | $\delta_1$ | $\lambda_1$ | $\phi_2$ | $\delta_2$ | $\lambda_2$ | Trend P | Plunge P | Trend T | Plunge T | STDR | $Q_f$ | $Q_p$ | FT |

We analyzed the effect of the velocity model on focal mechanism solutions; by using the Calcagnile and Panza (1980) velocity model retrieved for the Apulian lithosphere, used in the paper of Del Gaudio et al. (2007), we inferred some small variations, of the P and T-axes orientations, with respect to the above described results, only for few events of G1 group. This may be due to the shallow foci depth which gives rise to different values of take-off angles. No difference is obtained for G2 and G3 groups.

Table 4. List of composite fault plane solutions. The number of events ($N_{ev}$) used for the composite solution, the number of polarities ($N_{pol}$), strike $\phi$, dip $\delta$ and rake $\lambda$ of the 2 nodal planes, the trend and plunge of the P and T axes, the STDR, the quality factors ($Q_f$ and $Q_p$) and the fault type (FT) are reported.

| Nev | Npol | $\phi_1$ | $\phi_2$ | $\lambda_1$ | $\lambda_2$ | Trend P | Plunge P | Trend T | Plunge T | STDR | $Q_f$ | $Q_p$ | FT |

Fig. 3. Map of the Gargano area with the accepted focal mechanism solutions. Colors of the beach ball correspond to the single event focal mechanism (black), composite focal mechanism for the G1 group (blue), composite focal mechanism for the G2 group (yellow), composite focal mechanism for the G3 group (red). (Color figure online)
4 Stress Field in the Gargano Area

We performed the stress inversion of the available focal mechanisms by using the FMSI (Focal Mechanism Stress Inversion) package by Gephart (1990). This inversion scheme provides accurate estimates of the stress tensor since it resolves four of the six independent components of the stress tensor. This method allows to obtain the three eigenvectors, i.e. the maximum, the minimum and the intermediate compressive principal stress axis directions \( (\sigma_1, \sigma_3 \text{ and } \sigma_2) \), and one dimensionless parameter \( R = (\sigma_2 - \sigma_1)/(\sigma_3 - \sigma_1) \) which, combining the magnitudes of the principal stresses, constrains the shape of the stress ellipsoid. The \( R \) value ranges from \( R = 0 (\sigma_2 = \sigma_1) \) to \( R = 1 (\sigma_2 = \sigma_3) \).

The inversion uses the dataset of fault orientation to determine the best-fitting values of the four stress parameters. To better constrain the stress values obtained by the FMSI inversion, to each fault plane solution a weight was assigned. After several tests, we assigned to each datum the weight \( W_i = \sum W_i \) (the weights \( W_i \) are detailed in Table 5) that decreases with decreasing the quality factors and that increases with increasing the number of polarities.

We applied the two acceptance criteria of the stress solutions as proposed by Lu et al. (1997). The first criterion requires that the 95% confidence regions of the maximum and minimum principal directions must not overlap to consider as acceptable the solution. The second criterion, which account for the degree of heterogeneity of the investigated medium, requires that the misfit angle has not to exceed 6°. Only if these criteria hold, the stress solution can be considered homogeneous and acceptable.

The stress tensor inversion was applied to all three groups of events, defined in the preceding section and the results are listed and plotted in Fig. 4 and described below.

G1 Group. The stress field was inferred from the inversion of the 9 best constrained fault plane solutions. The 95% confidence regions of the solution are very narrow and the misfit = 3.86° indicates homogeneity of the medium. The axis of maximum compression \( \sigma_1 \), that is subvertical (vertical lithostatic stress orientation, \( S_v \)), together with the intermediate stress axis \( \sigma_2 \) (maximum horizontal compression orientation, \( S_{H_{\text{max}}} \)) and the minimum stress axis \( \sigma_3 \) (minimum horizontal compression orientation, \( S_{h_{\text{min}}} \)) indicate a normal faulting kinematics. \( R = 0.15 \) is very low and indicates that in the first 10 km of depth, in the southwestern Gargano, \( \sigma_1 \) and \( \sigma_2 \) have similar values, greater than \( \sigma_3 \) (Fig. 4).

| \( W_i = \{ Q_f, Q_p, N_{pol} \} \) | 3 | 2 | 0 | 1 | 2 | 3 |
|---|---|---|---|---|---|---|
| \( Q_f = A, Q_p = A \) | | | | | | |
| \( Q_f = B, Q_p = B \) | | | | | | |
| \( N_{pol} = 6 \) | | | | | | |
| \( N_{pol} = [7,8] \) | | | | | | |
| \( N_{pol} = [9,10] \) | | | | | | |
| \( N_{pol} \geq 11 \) | | | | | | |
G2 Group. The stress field was inferred from the inversion of the 15 best fault plane solutions. The 95% confidence regions of the solution don’t overlap and the very low misfit = 3.03° indicate homogeneity of the medium. The subvertical axis of minimum compression $\sigma_3$ ($S_v$) and the sub-horizontal stress axes $\sigma_1$ ($S_{H\text{max}}$) and $\sigma_2$ ($S_{h\text{min}}$) indicate a thrust faulting kinematics. $R = 0.3$ indicates that deeper in the crust, moving toward the northeastern Gargano, the kinematics changes and $s_1$ and $s_2$ begin to differ from each other but are still greater than $s_3$ (Fig. 4).

G3 Group. The stress field was inferred from the inversion of 13 fault plane solutions. The 95% confidence regions of the solution don’t overlap and the misfit = 4.91° indicates homogeneity of the deeper layers of the crust continuing toward northwestern in the Gargano. The subvertical axis of minimum compression $\sigma_3$ ($S_v$) and the sub-horizontal stress axes $\sigma_1$ ($S_{H\text{max}}$) and $\sigma_2$ ($S_{h\text{min}}$) indicate a thrust faulting kinematics, like that of G2 group. $R = 0.45$ indicates that $\sigma_2$ has an intermediate value between $\sigma_1$ and $\sigma_3$ (Fig. 4).

G2-G3 Group. We used the events of G2 and G3 groups, that brought similar results in terms of tectonic kinematics and output parameters, to obtain a unique stress field solution. Also in this case, the 95% confidence regions of the solution don’t overlap. The misfit = 5.72° represents the higher value among the considered groups, indicating a lower degree of homogeneity at depth between 15 and 25 km. The $R = 0.35$ is intermediate between the results of G2 and G3 groups, taken individually (Fig. 4). If we try to assemble the groups in order to include the G1 group, the results of the FMSI inversion fall outside the criteria of acceptability indicating a great heterogeneity of the focal mechanism data. In fact, if we unify the groups G1-G2, for a total of 24 focal mechanism solutions, the misfit is 6.64°; if we unify all the groups G1-G2-G3, for a total of 37 events, the misfit is 7.67°. Both the assemblages result in a misfit greater than the reference threshold of acceptability of 6°; therefore they have been both rejected.

---

**Fig. 4.** Results of the FMSI inversion for the three considered event groups (G1, G2 and G3) and for the merged group G2–G3. Angles of trend/plunge of the principal stress axes ($\sigma_1$, $\sigma_2$, $\sigma_3$) within 95% confidence area, the $R$ value and the misfit angle are indicated for each group.
5 Discussion and Conclusions

In previous works, the lateral dependence of microearthquake foci depths (Filippucci et al. 2019a), of the coda quality factor attenuation (Filippucci et al. 2019b) and of resistivity (Tripaldi 2020) was observed. Therefore, we can hypothesize that stress field exhibits the same dependence. The focal mechanism solutions show clear variation among the considered groups: for G1 group the kinematics is normal faulting, whereas for G2 and G3 groups the kinematics is thrust faulting (Fig. 3). The composite mechanism results, obtained for the three groups separately, indicate that the solutions are stable and confirm that the kinematics of faulting changes abruptly, i.e. in few tenths of kilometers, from normal to thrust (Fig. 3). This change corresponds also to the foci deepening (Fig. 2).

The stress field results also show an abrupt change in the horizontal maximum stress direction $S_{H\text{max}}$, since it passes from normal faulting NE-SW $S_{H\text{max}}$ oriented for G1 group, to a reverse faulting NW-SE $S_{H\text{max}}$ oriented for the G2 and G3 groups. This indicates a clockwise rotation of $S_{H\text{max}}$ moving deeper and toward the northeastern sector of the Gargano Promontory. By considering the groups G2 and G3 together, the maximum horizontal stress $S_{H\text{max}}$ is oriented in an intermediate angle between the two groups taken separately.

Previous studies of focal mechanisms and stress field in this area have been proposed. Frepoli and Amato (2000), by grouping the seismicity of a broader area including the Gargano Promontory, found a normal faulting kinematics with the horizontal maximum stress oriented as for the Apennine stress (plunge/trend: $\sigma_1 = 73/130$, $\sigma_2 = 17/310$, $\sigma_3 = 0/40$). Milano et al. (2005), by analyzing the seismicity of a more restricted area (including the Gargano Promontory), found a strike-slip kinematics with an oblique (normal/strike-slip) component and the stress solution indicates normal faulting ($\sigma_1 = 63/260$ and $\sigma_3 = 30/39$). Instead, Del Gaudio et al. (2007), from the analysis of $M_L > 1.6$ seismicity, found focal mechanisms of strike-slip kinematics with a slight normal component in the southwestern zone and a slight inverse component in the northeastern promontory. Overall, they obtained a unique strike-slip stress field solution ($\sigma_1 = 12/321$, $\sigma_2 = 55/69$, $\sigma_3 = 32/224$) for the area of the Gargano Promontory. Our results for G2 and G3 groups disagree with those found by Del Gaudio et al. (2007) regarding the faulting kinematics. In fact, the strike-slip component is completely absent in our solutions. However, our results confirm the orientation of $S_{H\text{max}}$ stress component found by Del Gaudio et al. (2007). This discrepancy may indicate the heterogeneity of the whole fault system. Our results do not agree with those of Milano et al. (2005) and of Frepoli and Amato (2000) in any of the areas covered by the three groups.

Considering G1 group, the kinematics is normal faulting, as characteristics of the Apennine chain, but $S_{H\text{max}}$ is normal to that of the Apennine stress orientation. This result was obtained with few events and needs further investigations since, in the area covered by G1 group, the available seismic catalogues are lacking. As concern G2 and
G3 groups, our results, in terms of trend and plunge of $S_{Hmax}$, agree with the Italian Stress Map (Montone and Mariucci 2016) even if we use a different event dataset covering a part of the Gargano Promontory, otherwise lacking information.

In order to check our results, a further inference of the stress orientation was done by adding the events of Del Gaudio et al. (2007) to our dataset. We selected only the events that fall in the volume of each group, separately. None of the events used by Del Gaudio et al. (2007) falls within the volume defined by G1 group while 4 events fall into the G2 group and 4 events into the G3 group. So, we repeated the stress inversion for the G2, G3 and for the combined G2-G3 groups (results in Fig. 5). Even if the heterogeneity of the focal mechanisms of each group increases (the misfit angle increases respect to that in Fig. 4), the results of thrust faulting are confirmed. The integration of our data with the focal mechanisms of Del Gaudio et al. (2007) indicates a slight heterogeneity of preexisting faults in the Gargano area but confirm the NW-SE thrust faulting.

The fault strike orientations in the Gargano area as inferred in this work and in the World Stress Map (WSM, Heidbach et al. 2018) disagree with the image of the surface traces of faults inferred in the area (Doglioni et al. 1994; Chilovi et al. 2000; Brankman and Aydin 2004; Patacca and Scandone 2004), indicating that the deep present-day micro-seismicity occurs on structures that are perpendicular to the mapped fault lines and to which the contractional tectonic evolution of the Gargano Promontory is attributed (Bertotti et al. 1999; Brankman and Aydin 2004; Billi et al. 2007). The disagreement between the present-day tectonic regime, as also recently sketched by Roselli et al. (2018), and the surface tectonic lines has been investigated by Billi et al.

Fig. 5. Results of the FMSI inversion for the considered groups of events including the events of the dataset of Del Gaudio et al. (2007) which belong to each group. Angles of trend/plunge of the principal stress axes $\sigma_1$, $\sigma_2$, $\sigma_3$) within 95% confidence area, the R value and the misfit angle are indicated for each group.

| Group | $\sigma_1$ | $\sigma_2$ | $\sigma_3$ | R | Misfit |
|-------|------------|------------|------------|---|--------|
| G2    | 322°/10°   | 231°/2°    | 132°/80°   | 0.30 | 4.17°  |
| G3    | 126°/0°    | 216°/10°   | 36°/72°    | 0.4  | 6.19°  |
| G2-G3 | 311°/5°    | 219°/17°   | 72°/57°    | 0.4  | 6.41°  |
(2007) who considered, as present-day kinematics, the normal fault regime found by Milano et al. (2005). Results however don’t agree both with our study and with the WSM. So further geodynamical investigations are needed. The only way to better constrain the issues arising from this study is to pile up further events through the seismic monitoring of the Gargano area with a dense and modern seismometer array.
