ABSTRACT

The first detection of the period doubling phenomenon is reported in the Kepler RR Lyrae stars RR Lyr, V808 Cyg and V355 Lyr. Interestingly, all these pulsating stars show Blazhko modulation. The period doubling manifests itself as alternating maxima and minima of the pulsational cycles in the light curve, as well as through the appearance of half-integer frequencies located halfway between the main pulsation period and its harmonics in the frequency spectrum. The effect was found to be stronger during certain phases of the modulation cycle. We were able to reproduce the period doubling bifurcation in our nonlinear RR Lyrae models computed by the Florida-Budapest hydrocode. This enabled us to trace the origin of this instability in RR Lyrae stars to a resonance, namely a 9:2 resonance between the fundamental mode and a high-order (9th) radial overtone showing strange-mode characteristics. We discuss the connection of this new type of variation to the mysterious Blazhko effect and argue that it may give us fresh insights to solve this century-old enigma.

Key words: Kepler – instabilities – stars: oscillations – stars: variables: RR Lyr – stars individual: RR Lyrae – stars individual: V808 Cyg – stars individual: V355 Lyr.

1 INTRODUCTION

The unprecedented power of the Kepler space telescope in terms of precision and continuity is poised to deliver major breakthroughs in exoplanet science (Borucki et al. 2010) and stellar photometry (Gilliland et al. 2010a) allowing exploration of territories never tested before. New instruments often reveal surprising new phenomena and lead to new insights in (astro)physical problems. Such an unforeseen feature, period doubling (hereafter PD) and the corresponding half-integer frequencies (hereafter HIFs) were reported by Kolenberg et al. (2010a) in the Kepler Q1 data (34 days) of RR Lyr, the prototype, brightest Blazhko-type RR Lyrae star in the sky.

It has been well known for decades that high-order overtones in RR Lyrae stars can show Blazhko modulation. This phenomenon is characterized by the appearance of secondary maxima and minima in the light curve, which are usually attributed to the excitation of high radial overtones. However, the origin of this modulation is still a matter of debate. Some authors suggest that the Blazhko effect is caused by the excitation of high radial overtones (Szabó et al. 2009), while others argue that it is due to the interaction of the fundamental mode with high radial overtones (Kolenberg et al. 2010a).

The period doubling phenomenon is not to be confused with double-mode pulsation, where two radial modes (of low order) are excited simultaneously.

luminosity RV Tauri variables show alternating deep and shallow minima in their light and radial velocity curves. Buchler & Kovács (1985) and Kovács & Buchler (1988) carried out the first systematic search of irregular oscillations in radiative and strongly dissipative Pop. I (W Vir) models. They demonstrated that the pulsations in those models undergo a Feigenbaum cascade of period doubling bifurcations by changing the control parameter (effective temperature). That is to say the instability develops from strict periodic pulsation to period-two, period-four etc., oscillations resulting in low dimensional chaos.

Moskalik & Buchler (1990, 1991) and Buchler & Moskalik (1992) reported period doubling bifurcation, as well, in purely radiative Cepheid and BL Her model sequences. By changing the control parameter (Teff), their weakly dissipative Pop. I. Cepheid models showed the onset of period doubling and a subsequent reversion to period-one oscillations instead of further period-doubling episodes, in contrast with the more dissipative models.

Nonlinear stable periodic pulsations (limit cycles) can be made to ‘period double’ through the destabilization of either a thermal (real) mode or an additional (complex) vibrational mode. Moskalik & Buchler (1990) could trace the origin of the PD to be a destabilized low-lying vibrational overtone and that the coupling occurs through an internal resonance of the type (2n+1)ωk ≈ 2ωk where n is an integer (1 or 2) and the subscripts 0 and k refer to the fundamental and the kth overtone modes, respectively. In this case the parametric instability of an overtone pulsation mode in half-integer resonance opens up an additional dimension which allows the limit cycle to period double.

In this paper we describe our discovery of the period doubling phenomenon in three RR Lyrae variables observed by the Kepler space telescope. One of them is RR Lyr (KIC7198959, Kepler mag: 7.9) the prototype of its class, V808 Cyg (KIC484128) and V355 Lyr (KIC7505345). The two other RRab stars are of much fainter apparent brightness: Kp=15.4 and 14.1, respectively. Four additional Kepler RR Lyrae stars show weak signs of the period-doubling phenomenon. All those objects show the enigmatic Blazhko effect, i.e., amplitude and phase modulation of the regular RR Lyrae pulsation. For the recent Kepler findings with respect to RR Lyr itself and an overview of the Blazhko effect, we refer to Kolenberg et al. (2010) and Benkó et al. (2010), respectively.

Since resonances are known to play much less of a role in RR Lyrae stars than in Cepheids, it is natural to ask whether occurrence of any type of resonance between radial modes can cause this behavior. Serendipitously, we encountered RR Lyrae models showing the PD bifurcation and subsequently we applied them to the Kepler RR Lyrae stars. We were able to demonstrate that in RR Lyrae stars the physical origin of this instability is a 9:2 resonance between the fundamental mode and a high-order radial overtone. This latter mode is called a strange mode (Buchler & Kolláth 2001), because it has no adiabatic counterpart and the energy associated with its pulsation is confined to the outer zones of the star. The goal of this work is to present the first Kepler RR Lyrae period doubling results and our first successful modeling efforts.

The outline of this paper is as follows. In Sec. 2 we describe Kepler observations we use and devote special emphasis to reduction and proper handling of Kepler photometry. In the next section the observed properties of the period doubling are presented. Next we turn to hydrodynamical models that successfully reproduce the newly discovered phenomenon in Sec. 3. Finally, the implications of using this transient phenomenon to gain insight to the enigmatic Blazhko effect are explored.

2 OBSERVATIONS

Kepler was designed to detect transits of terrestrial planets on Earth-like orbits around solar-like stars. This requires the observation of ~ 10^5 main sequence stars continuously for several years with great accuracy. Kepler was launched on 2009 March 6, and observes a 105 square degree area of the sky in constellations Cygnus and Lyra, a few degrees above the galactic plane. After a short commissioning phase, the scientific observations started on May 12. In order to ensure optimal solar irradiation of the solar arrays, a 90 degree roll of the telescope is performed at the end of each quarter. The first roll lasted only for 33.5 days (Q1). The second roll was the first complete one (Q2). In this work we use both Q1 and Q2 when available, i.e., 127 days quasi-continuous observations.

The Kepler magnitude system (Kp) refers to the wide pass band (430 – 900 nm) transmission of the telescope and detector system. Both long-cadence (LC, 29.4 min, Jenkins et al. 2010), and short-cadence (SC, 58.9 s, Gilliland et al. 2010b) observations are based on the same 6-s integrations which are summed to form the LC and SC data onboard. In this work we used only long-cadence data. The saturation limit is between Kp ≈ 11 – 12 mag depending on the particular chip on which the star is observed; brighter than this, accurate photometry can be performed up to Kp ≈ 7 mag with judiciously designed apertures.

The Kepler Asteroseismic Science Consortium (KASC) was set up to exploit the potential of Kepler in solar-like oscillations as well as all types of pulsations. KASC Working Group#13 is dedicated to the investigation of RR Lyrae stars. Out of 29 RRab stars that were observed by Kepler 14 were found to be Blazhko stars. Small gaps are seen in their light curves (Fig. 3). These are due to unplanned safe mode and loss of fine point events as well as regular data downlink periods. Excluding these cadences, the Q1 data segment contains 1626 useful data points, while Q2 contains 4097 points.

Our trend and jump filtering algorithm was tested on the Kepler data. We found that no detrending was necessary for our targets. Jump corrections were also considered unnecessary for our purposes. We noticed that Q1 and Q2 mean brightness and amplitudes of a given pulsating star may differ. For our fainter targets only the mean brightness had to be adjusted between different rolls. In the case of RR Lyr, however a more thorough analysis and calibration was needed.

2.1 Accurate photometry of bright Kepler targets

As we mentioned before, Kepler CCDs saturate between Kp ≃ 11 and 12 mag, but the saturated flux is conserved to a very high degree, spilling in the column direction. This
Table 1. Main properties of the observed Kepler Blazhko RR Lyrae stars showing the period doubling effect. Errors are given in parenthesis implying variation in the last digit only. The uncertainty of the Blazhko period is estimated to be $0.13$.

Figure 2. The flux summed along the left-adjacent (blue dashed) and right-adjacent (red) columns to the central column. The incident stellar flux in these adjacent columns was fully captured.

Period doubling in Kepler RR Lyrae stars

allows Kepler to perform high-precision photometry on saturated targets like RR Lyr as long as a sufficient number of pixels is captured in the column direction. In Q1 and Q2, a fraction of flux from RR Lyr fell outside the Kepler aperture (set of downlinked pixels), so extra care is required to assure that the period doubling phenomenon is not due to loss of flux in some cadences. We developed an approach that estimates a correction of the RR Lyr flux. Part of the original and corrected light curve is shown in Fig. 1. The details of this method are described in Kolenberg et al. (2010).

Here we only note that in Q1 the flux corrections in case of the RR Lyr were less than 5%, while in Q2 the necessary flux corrections were larger, ranging from 15% to 35%. The uncertainty in the total corrected flux is about 0.25%. This is to be compared with the flux uncertainty of $8 \times 10^{-6}$ in cadences where the correction was not applied because the flux was completely captured. For comparison the uncertainty of the (uncorrected) flux for the two fainter stars showing the period doubling varies between $3 - 7 \times 10^{-4}$ for V808 Cyg and $1.5 - 3.1 \times 10^{-4}$ for V355 Lyr.

Because these corrections are estimates, we provide the following evidence that the period doubling phenomenon in Q2 RR Lyr data is not due to loss of flux:

- Similar alternating cycles are seen in the flux time series of individual pixels, as well as the sum of pixels along columns with significant flux (other than the central column) from RR Lyr (see Fig. 2). In individual pixels, the period doubling signal is much larger than the pixel-level noise, which is dominated by pointing jitter and shot noise.
- Saturated pixels induce a faint video crosstalk signal on other CCD channels. At its maximum, crosstalk from the saturated flux from RR Lyr impinged on a faint observed target, and this crosstalk signal is consistent with the reconstructed light curve including period doubling.
- Kepler light curves are created using pixels in a photometrically optimal aperture that maximizes the signal to noise ratio for the target (Bryson et al. 2010). Kepler downlinks a superset of these pixels including at least a 1-pixel halo around the photometrically optimal aperture. In the case of Q1 and Q2 observations of RR Lyr, significantly more pixels were downlinked. Flux light curves created using all downlinked pixels exhibit essentially the same period doubling phenomenon as the light curve generated from the photometrically optimal pixels. This demonstrates that period doubling is not due to loss of flux from the (smaller) optimal aperture other than the central saturated column.
- Perhaps the strongest evidence that period doubling is not due to loss of flux is that the period doubling phenomenon was seen in Q1 when the flux from RR Lyr was completely captured.
- The fact that three stars were found unambiguously showing the PD effect further helps in ruling out external influences. The bright RR Lyr and the two much fainter stars (V808 Cyg and V355 Lyr) demonstrate that the same effect is operational at two different parts of the dynamical range of the CCDs. In addition, all three stars fell on different CCD-modules and the modules were rotated be-
tween Q1 and Q2, so the PD effect is independent of the CCD-modules.

Based on the analysis described in this section, we have high confidence that the period doubling phenomenon is not due to instrumental effects.

3 THE PERIOD DOUBLING PHENOMENON

3.1 Alternating extrema and half-integer frequencies

Period doubling is found in three of the Blazhko stars in the Kepler field: RR Lyr (KIC 7198959), V808 Cyg (KIC 4484128) and V355 Lyr (KIC 7505345). Some of their properties can be found in Table 2. The pulsational period, the Blazhko period and the amplitude of the first Fourier-component ($A_1$) were derived from the available Kepler observations. These numbers will be refined with more Kepler data.

The upper panels of Figs 3 and 4 show the Q1+Q2 light curves for RR Lyr and V808 Cyg in the $K_p$ band. The individual maxima and minima were fitted with a 9th order polynomial to test the effect of the 29.4-min sampling which may undersample the rapidly changing light curve around the maxima. We find no significant problem arising from the long-cadence sampling. Certain parts of the light curves are marked with dotted line rectangles and are magnified to discern the alternating maxima and minima in Figs 3 and 4. The fitted maxima and minima are plotted as horizontal bars to guide the eye in these figures. In the case of RR Lyr a difference of 0.3 m is seen in the brightness of subsequent maxima. This amounts to a few hundredths of magnitude in case of V808 Cyg.

The alternating maxima and minima in conjunction with the half-integer frequencies (HIFs, i.e., $k/2 \cdot f_0$, where $k = 1, 3, 5, \ldots$) in the frequency spectrum are typical signs of the period doubling bifurcation. For the frequency analysis we used SigSpec (Reegen 2007). Where available, Q1 and Q2 data sets were merged. When the spectral significance reached the conservative value $5$ the procedure was stopped, although the traces of HIFs can be followed up to the Nyquist-frequency (24.5 c/d). The results were checked by Period04 (Lenz & Breger 2003). Only minor differences were found, mainly in the phase values.

In our third case, V355 Lyr, the PD effect is undoubtedly present, but is rather weak (Fig. 7). The maximum

Figure 3. Upper panel: Q1+Q2 light curve of RR Lyr. Note that the individual pulsational cycles are hardly discernible, while the long period (39.6d) Blazhko modulation clearly stands out. The three dashed boxes are blown-up in Fig. 4. Bottom panel: amplitudes of the half-integer frequencies.

Figure 4. Seven-day segments of the Kepler light curve of RR Lyr showing different degree of period doubling effect at the same Blazhko phase. The maxima and the minima were fitted with a 9th order polynomial and the small horizontal bars drawn through the extrema are plotted to guide the eye.
amplitude of the $3/2 f_0$ frequency is 5 mmag, while it is 25 mmag for the two other targets. This translates to a few hundredths of a magnitude difference in consecutive maxima or minima. Interestingly, the amplitude modulation is also small for this star.

Four other Blazhko RR Lyrae stars in the Kepler field are seen to possibly exhibit the PD effect: V2178 Cyg (KIC 3864443), V354 Lyr (KIC 6183128), V445 Lyr (KIC 6186029) and V360 Lyr (KIC 9697825). In their frequency spectra peaks were found close to the predicted half-integer frequencies. However, our criteria for the detection of the PD effect were the clear sign of alternating height of the pulsation cycles as well as the simultaneous presence of a large number of HIFs (preferably more than eight). If any of these two requirements were not met by a star, we consider it as a possible PD object only. We note that some of these four stars in this category show additional frequencies making their frequency spectrum more complex. For more details on these stars we refer to Benkő et al. (2010).

From now on we turn to our three stars that show securely detected PD phenomenon. We plotted the averaged amplitudes of the HIFs of these stars in Fig. 8 taken from their frequency spectra. It is interesting to note that in all three cases the $3/2 f_0$ frequency has the highest amplitude among the half-integer frequency peaks, next comes $5/2 f_0$ and $1/2 f_0$. This appears to be a general feature of the PD phenomenon in Blazhko stars. Around the fifth half-integer frequency, (i.e., $k = 9$) a pronounced bump is seen in the amplitude distribution. The origin of this bump is explained in detail in Sec. 4. The amplitude of the higher-order half-integer peaks are decreasing more or less steadily with the order number $k$.

### 3.2 The transient nature of the period doubling

After discussing the time-averaged properties of the HIFs we now turn to investigate their temporal behavior. The lower panels of Figs 3 and 5 for RR Lyr and V808 Cyg respectively, show the temporal behavior of the amplitude of the most prominent half-integer frequencies in the frequency spectra. These were computed using the analytic signal method (Kolláth et al. 2002), a powerful method developed to follow time-dependent signals. We note here that the method is superior compared to other time-dependent Fourier-methods, but has a drawback: in the presence of large gaps the procedure does not yield reliable results, therefore we had to cut the neighborhood of the missing data. We found a 0.25 c/d bandwidth to give the most stable results, and a $\sim 2.5$ d long data segment is lost in each side of a gap. The relatively broad bandwidth means that sometimes more than one frequency peak is contained in the computed interval.
but the insensitivity to noise compensates for this disadvantage. We tested that the temporal behavior of the HIFs is not flawed by the chosen bandwidth.

It is obvious from Figs. 3 and 4 that the intensity of the period doubling phenomenon is changing with time. For RR Lyr it has maximum strength on the ascending branch of the Blazhko envelope on the first two rising branches, and is much less visible during the third ascending branch of the Blazhko modulation. The difference in brightness between consecutive maxima reaches as high as 0.1 mag when PD is strongest. The visible alternating extrema can be seen where the amplitude of the HIFs is high, and no significant alternation is found where the amplitude is low. This is true for all our target stars throughout the whole light curve in each case. In RR Lyr the amplitudes of the HIFs never vanish, in other words the PD effect is always present. Fig. 4 demonstrates the difference of the strength of the HIFs showing the discrete Fourier transforms of the second and third marked segments of the RR Lyn light curve as shown in Fig. 3. We prewhitened with the main pulsation frequency and its harmonics (but not with the Blazhko side-peaks) for better visibility of the HIFs. It is discernible that the half-integer frequencies are present in both data segments, with a factor of three difference in the amplitudes. We can conclude that the PD effect is transient and varies with the Blazhko cycle.

In the case of V808 Cyg the PD effect is practically seen throughout the whole 133-d observational period, albeit with outstanding maxima of the HIFs during the ascending branch of the Blazhko envelope, close to the Blazhko maximum and during the descending branch. The minimum level of the half-integer frequencies is not as low as for RR Lyr, but the maximum height is similar. Again, there is a clear connection of the PD effect to the Blazhko modulation, very similar to the case of RR Lyn, but with enhanced intensity and an additional maximum height during the descending branch of the Blazhko envelope.

One can see numerous peaks in the vicinity of the half-integer frequencies (Fig. 11). In addition, we noticed that the highest frequency peak has a frequency ratio to \( f_0 \) that is significantly different from 2/3, namely 0.662. This is the combined effect of the Blazhko modulation and the temporal onset and disappearance of the HIFs. To test this hypothesis we performed the following check.

We generated an artificial light curve sampled at the original data points. We took \( f_0 \) and its 16 harmonics of RR Lyn, their phases and amplitudes and modulated the amplitude and the phase with a Fourier-sum of two terms and five terms, respectively. The resulting light curve is very similar to the observed one, but we note that the purpose of this simulation was to explain the frequency spectrum in the vicinity of the HIFs and not the reproduction of the light curve.

Then we added the 1/2 \( f_0 \), 3/2 \( f_0 \), 5/2 \( f_0 \) etc. frequency series with small amplitude. The same modulation is applied to these periodic signals, as well. We used \( f_0 = 1.762989 \) c/d in the simulation and applied MuFrAn for the frequency analysis. It resulted in \( f_0' = 1.763059 \) c/d. We prewhitened the light curve with \( f_0' \) and its 16 harmonics. The resulting spectrum between \( f_0 \) and 2\( f_0 \) is shown in the upper panel of Fig. 10 where additional small peaks appear around 3/2 \( f_0 \).

The middle panel shows the result of a similar procedure, but here the period-doubling (i.e., the HIFs) was switched on and off periodically. Specifically, the amplitudes of the HIFs were varied as \( a = \sin(f_m \cdot t + \phi) \) if \( a > 0 \) and \( a = 0 \) otherwise, i.e., HIFs are present only when the function is positive. \( f_m \) denotes the modulation frequency. One can find at least 5 distinct peaks in the synthetic spectrum, the highest two of them are of similar amplitude. The frequencies of these peaks are: \( f' = 2.6432455 \) c/d and \( f'' = 2.6701858 \) c/d, their frequency ratios are: \( f'/f_0 = 0.667 \) and \( f''/f_0 = 0.660 \), respectively.

Our simulation demonstrated convincingly that the large number of frequency peaks and the frequency ratio close to but not equal to 2/3 are expected consequences of the modulated light curve, and we are dealing with a genuine period doubling effect.

Summarizing our findings concerning the PD effect in three Kepler Blazhko RRab stars we conclude that this effect occurs in some but not all modulated RR Lynae stars. For a given star its presence may be continuous, but there are specific phases of the Blazhko cycle, where it gets much stronger (up to five times in amplitude). This is not a strict
rule, however. Out of three rising branches of the Blazhko modulation (i.e., envelope) in RR Lyr we detected a strong presence of PD in the first two cases, and much weaker appearance during the third one. The overall dominance of the period doubling may also vary, for RR Lyr and V808 Cyg it is relatively strong, while for V355 Lyr it is much weaker.

3.3 Detection limit in the Kepler sample

Upper limits for the averaged amplitudes of half-integer frequencies were established for all the Kepler RR Lyrae stars where we did not find PD effect. Frequency spectra were computed for the 14 Blazhko and 15 non-Blazhko Kepler RR Lyrae stars) using SigSpec and prewhitened successively with the highest frequency peaks. These were the dominant pulsational mode (fundamental in each cases), its harmonics up to the Nyquist-frequency and modulation side peaks in case of Blazhko stars. The procedure was stopped when the amplitudes of the remaining peaks reached a spectral significance of 5.0. As the limit for the HIF amplitudes we accept the amplitude corresponding to this spectral significance limit. We emphasize that this choice is conservative, because inspection of the location of the HIFs showed that there were no frequency peaks up to an amplitude two to three times lower than our adopted limit of 5.0.

Two factors affect our detection limit, one is the brightness of the star and the other the complexity of the frequency spectrum (see Benkó et al. 2010). We note in passing that the apparent magnitudes of the Kepler RR Lyrae sample are in the range of $K_p \simeq 11 - 17$, the notable exception being RR Lyr, which is much brighter. Another source of error may be the lack of barycentric correction to the (shorter) Q1 time series. While this is correction is important, we argue that it has no effect on our detection limit. First because it does not effect the alternating maxima and minima. Second, although it may cause some systematics in the frequency spectrum, the basic structure of the HIFs is well understood, as we demonstrated in the previous subsection.

As we mentioned in Sec. 3.1, we found four additional stars showing some HIFs besides RR Lyr, V808 Cyg and V355 Lyr. For the remaining Blazhko stars not showing the PD effect we find that the upper limit for the HIF amplitudes is between 0.2–2.0 mmag. For RR Lyrae stars without modulation we generally find a smaller upper limit. The detection limit for these objects is between 0.1–1.0 mmag, with more stars lying closer to the 0.1 mmag border line.

We have not found period doubling bifurcation in the ultra-high precision light curve of any of the non-Blazhko stars, in spite of the fact that it would be much easier to discern alternating extrema, as well as HIFs in their frequency spectra. In conclusion, these findings strongly suggest that the PD bifurcation is related to the Blazhko effect.

4 HYDRODYNAMICAL SIMULATIONS

Hydrodynamical modeling has proved that low order resonance plays an important role in the oscillations of classical pulsating stars. The Hertzsprung progression of bump Cepheids is traced to the $P_3/P_2=2$ resonance (e.g. Buchler et al. 1990). The sharp features in the Fourier coefficients of s-Cepheids are traced to the $P_4/P_3 = 2$ reso-
nance, despite the very large damping of the fourth overtone (Feuchtiger et al. 2000). In the case of BL Her and Cepheid type pulsations it was demonstrated by Moskalik & Buchler (1990) that 3:2 resonance of the fundamental mode and the first overtone is responsible for period doubling bifurcation in hydrodynamical models.

However, only the low order modes up to the 4th overtone were considered when resonances were discussed, and the remaining modes were assumed to have no influence on the asymptotic behavior of the models since they are strongly damped.

In RR Lyrae stars, effects due to the above mentioned resonances are not expected because of the different period ratios. However, in some of the RR Lyrae model sequences period doubling bifurcation was detected, indicating that indeed there exists some mechanism that is able to destabilize the fundamental mode pulsations. To pinpoint the mechanism behind the period doubling bifurcation we have performed a systematic survey of RR Lyrae model sequences. The details of these calculations are presented elsewhere (Kolláth, Molnár & Szabó 2010), here we present only the results relevant to this paper. For our hydrodynamical calculations we used our standard turbulent convection stellar pulsation hydro-code (Florida-Budapest code, see Kolláth et al. 2002, Eqs. 1–13.) The main model parameters are $M = 0.578 M_\odot$, $L = 38.45 L_\odot$, $T_{\text{eff}} = 6500 K$, and metallicity: $Z = 0.0001$.

Standard integration of the models with PD behavior evolve to the bifurcated solution and thus the fundamental mode limit cycle cannot be calculated in this way. However, the relaxation method (see Kovács & Buchler 1993) makes it possible to iterate to the limit cycle solution and determine its stability properties. These calculations indicate that the fundamental mode limit cycle is unstable for a wide range of the model parameters. The large value of one of the Floquet exponents ($\lambda_k \approx 0.5$) indicates that perturbations to the limit cycle grow on a time scale of a few periods. Time integration of the model initiated from the limit cycle solution clearly demonstrates the short timescale of the transition from limit cycle to period-2 solution. The luminosity variation during this transition is displayed in Fig. 11. The perturbation to the limit cycle was defined as a 1% increase of eddy viscosity in the model. We have to note, however, that with no direct perturbation the model also evolves to the PD solution on a slightly longer timescale due to the numerical noise of the computations.

The numerical integration of the model clearly demonstrates the PD bifurcation in our RR Lyrae model. However, it does not provide a direct clue on the destabilizing mechanism of the fundamental mode. The PD bifurcation can occur through the destabilization of either a thermal mode or a vibrational mode. The second case was thoroughly described by Moskalik & Buchler (1990), showing that a half-integer resonance provides the mechanism in period doubling bifurcation in hydrodynamical models. The Floquet coefficient that gives the instability of the limit cycle is real (the Floquet phase, $\phi_k = \pi$). It indicates that the coupling to a vibrational mode is in effect through a half integer resonance, but it does not rule out the possibility of a thermal mode behind the PD behavior. Resonance is not expected in the low order modes, however, the linear stability analysis of the model sequences shows that some of the higher (8th-10th) overtones are unstable for some of the temperatures. This behavior of the linear models indicates that a strange mode coexists with the normal vibrational modes, suggesting that a resonance with this strange mode can be responsible for the destabilization of the fundamental mode.

In Fig. 12 the period ratios $P_3/P_k$ are displayed for the high-order modes. The period ratio curves show signatures of avoided crossings proving the existence of a strange mode (Buchler & Kolláth 2001). Interestingly, it clearly shows a half integer resonance with $P_3 : P_k = 9 : 2$ in a wide temperature range, which was not expected to provide such a strong influence on fundamental mode pulsation. A thorough nonlinear hydrodynamical survey of model sequences demonstrates that indeed this resonance provides the destabilization of the fundamental mode and it causes the period doubling bifurcation. Details of these calculations are presented in a parallel paper (Kolláth, Molnár & Szabó 2010).

The PD behavior strongly depends on the parameters of turbulent convection. Using e.g., the eddy viscosity as a control parameter, the bifurcation from limit cycle to period doubling is obtained. Similarly the convective efficiency can play an important role as a control parameter. If one assumes that during the Blazhko cycle the turbulent/convective structure of the star varies (Stothers 2006), it can result in the repeated occurrence of PD similarly to the observations.
Period doubling in Kepler RR Lyrae stars

5 DISCUSSION

The high precision and continuity of the Kepler space telescope has enabled us to discover a new phenomenon in Blazhko RR Lyrae stars, namely period doubling. Three stars were found to show this type of behavior unambiguously. One of them is the brightest representative of its class RR Lyr (KIC 7198959) and the other two are much fainter modulated RRab variables, namely V808 Cyg (KIC 4484128) and V355 Lyr (KIC 7505345). In addition, four other Blazhko RR Lyrae stars in the Kepler field may show signs of this new type of instability.

Period doubling manifests itself as alternating maxima and minima of pulsational cycles, sometimes even the shape of the light curve is alternating. As a consequence, the Fourier spectrum contains half-integer frequencies (HIFs), i.e., frequency peaks midway between harmonics of the main pulsational frequency.

Interestingly enough, the intensity of the PD effect is time-dependent. In RR Lyr it is most prominent during the ascending branch of the modulation in two Blazhko cycles, while it is practically missing during the third ascending branch. In V808 Cyg the PD effect is seen throughout the whole 133-d long data set, albeit with outstanding maxima of the half-integer frequencies during the ascending branch close to the Blazhko maximum and during the descending branch. In V355 Lyr the PD effect is present, but it is rather weak, the maximum amplitude of the 3/2 \( f_0 \) frequency is five times less than in the case of the two other targets. Similarly, the amplitude modulation is also rather small for V355 Lyr. This may hint at an intimate connection between the strength and of the Blazhko modulation and the period-doubling effect. Also, the fact that no PD effect was found in non-Blazhko Kepler RRab stars strongly suggests that this effect is connected to the Blazhko effect.

The structure of the HIFs in the spectrum is found to be rather complex. We successfully demonstrated that the bunch of appearing frequency peaks in the vicinity of the expected HIFs is due to the varying pulsational period throughout the modulation cycle, as well as the transient nature of the period doubling phenomenon.

Although deviations from regular single-periodic pulsation, i.e., cycle-to-cycle variations in RR Lyrae radial velocity curves (Chadid 2000) and irregularities in photometric observations (Jurcsik et al. 2008) had already been detected from the ground, one might ask why the PD effect was not discovered despite the fact that the difference of the subsequent maxima during the PD episode may well be observable from the ground with accurate CCD photometry. Firstly, 3/2 \( f_0 \) (the highest half-integer frequency in all three PD Blazhko stars) grows to 26 mmag in the Fourier-spectrum of RR Lyr when it shows maximum power. It may be visible only in well-sampled (essentially continuous) light curves which is very hard to obtain. Before MOST, CoRoT and Kepler no continuous RR Lyrae light curve was available. The compact, dedicated single-site observations (Jurcsik et al. 2005, 2008) and the limited multisite campaigns that have been organized for RR Lyrae stars (Kolenberg et al. 2006, 2009) did not yield the required coverage and accuracy to be able to detect the PD phenomenon. Secondly, pulsation periods close to 0.5 (typical for RR Lyrae stars) may hamper the detection, as from the ground one can follow only even or odd cycles every night and the duration of the maximum strength of the PD phenomenon as we see in Kepler data is not long (typically 8–10 d). Finally, period doubling itself is a transient phenomenon, not seen in every Blazhko cycles. We estimate that the maximum PD strength phase (i.e., possibly observable from the ground) lasts from 10% (RR Lyr) to 22% (V808 Cyg) of the currently available time span covered by Kepler observations. That’s where the continuity and longevity of Kepler observations have unbeatable advantage. In addition, strong PD occurs only in three stars out of 14 RR Lyrae exhibiting the Blazhko modulation, while four additional modulated RR Lyrae stars show much weaker evidence for PD-like behavior. We conclude that it is not surprising that the transient PD effect remained unnoticed in decades-long ground-based RR Lyrae observations.

The period-doubling bifurcation was reproduced successfully with the Florida-Budapest hydrocode which accounts for turbulent convection. We emphasize that not only the period doubling effect occurs naturally in our hydrodynamical models, but the time scale of the onset and fade-out of the PD effect is excellently reproduced, as well.

Our models of RR Lyrae stars demonstrated that period doubling is possible in these stars due to a 9:2 resonance of the fundamental and a high order (9th overtone) mode. It was not expected that such a high order mode plays an important role in fundamental mode pulsations. However, it was found that this interacting mode is a strange mode, with a non-normal damping rate and eigenfunction. Normal high order pulsation modes, with this extreme period ratio \( (P_0 : P_k = 9 : 2) \), are not able to destabilize the fundamental mode limit cycle and to induce a period doubling bifurcation. Thus the observed period doubling characteristic in the Kepler RR Lyrae stars provides a strong indirect evidence for the existence of strange modes in radial stellar pulsation, a phenomenon predicted theoretically by Buchler et al. (1999). The significant interaction of the strange mode to the fundamental mode pulsation also suggests that strange modes can play an important role in other phenomena, like three-mode resonances (e.g., among the fundamental, 1st/2nd, and the strange mode); and perhaps it has an effect in shaping the Blazhko effect as well. In addition, nonradial modes may also be involved in this com-
complex dynamical interplay through resonant or non resonant interactions, as demonstrated by recent Kepler findings in Benkő et al. (2010).

We note that we found the strongest phase (or equivalently period) modulation in the cases of RR Lyr and V808 Cyg among Kepler Blazhko stars (Benkő et al. 2010), and these stars show the strongest PD effect. If we assume that during the Blazhko cycle the turbulent/convective structure of the star varies as suggested by Stothers (2006), it seems natural that in certain Blazhko phases (i.e., when the physical conditions are favorable) the PD effect appears, because in our models the PD behavior strongly depends on the parameters of turbulent convection. This sensitivity, together with the narrow parameter range where the necessary ($P_0 : P_k = 9 : 2$) resonance is at work make this new-found phenomenon a precious tool for studying the mysterious Blazhko effect.

The understanding of the differences between PD and non-PD Blazhko RR Lyrae stars, as well as the strong and feeble PD phases of a given star may provide the long-sought insight into the Blazhko mechanism, offering a sensitive way to constrain our models.

With the release of additional Kepler data it will be possible to further study the PD behavior and learn more about its temporal and transient nature.

ACKNOWLEDGMENTS

Funding for this Discovery mission is provided by NASA’s Science Mission Directorate. This project has been supported by the National Office for Research and Technology through the Hungarian Space Office Grant No. URK09350 and the ‘Lendület’ program of the Hungarian Academy of Sciences. KK acknowledges the support of Austrian FWF projects T359 and P19962. The authors gratefully acknowledge the entire Kepler team, whose outstanding efforts have made these results possible.
