Risk Factors for Hemorrhagic Complications following Pipeline Embolization Device Treatment of Intracranial Aneurysms: Results from the International Retrospective Study of the Pipeline Embolization Device

W. Brinjikji, G. Lanzino, H.J. Cloft, A.H. Siddiqui, and D.F. Kallmes

ABSTRACT

BACKGROUND AND PURPOSE: Spontaneous intraparenchymal hemorrhage is a dreaded complication of unknown etiology following flow-diversion treatment. Using the International Retrospective Study of the Pipeline Embolization Device registry, we studied demographic, aneurysm, and procedural characteristics associated with intraparenchymal hemorrhage following Pipeline Embolization Device treatment.

MATERIALS AND METHODS: We identified patients in the International Retrospective Study of the Pipeline Embolization Device registry with intraparenchymal hemorrhage unrelated to index aneurysm rupture post-Pipeline Embolization Device treatment. The rate of intraparenchymal hemorrhage was determined by baseline demographics, comorbidities, aneurysm characteristics, and procedural characteristics (including anticoagulation use, platelet testing, number of devices used, sheaths, catheters, and guidewires). Categoric variables were compared with \( \chi^2 \) testing, and continuous variables were compared with the Student \( t \) test.

RESULTS: Of 793 patients with 906 aneurysms, 20 (2.5%) had intraparenchymal hemorrhage. Fifteen intraparenchymal hemorrhages (75.0%) occurred within 30 days of treatment (median, 5 days; range, 0–150 days). Nine patients with intraparenchymal hemorrhage (45.0%) died, 10 (50.0%) had major neurologic morbidity, and 1 had minor neurologic morbidity (5.0%). Intraparenchymal hemorrhage was ipsilateral to the Pipeline Embolization Device in 16 patients (80%) and contralateral in 3 patients (15.0%). Variables associated with higher odds of intraparenchymal hemorrhage included treatment of ruptured aneurysms (OR, 4.44; 95% CI, 1.65–11.94; \( P = .005 \)) and the use of \( \geq 3 \) Pipeline Embolization Devices (OR, 4.10; 95% CI, 1.34–12.58; \( P = .04 \)). The Shuttle sheath was not associated with intraparenchymal hemorrhage (OR, 0.97; 95% CI, 0.38–2.45; \( P = .95 \)).

CONCLUSIONS: Spontaneous intraparenchymal hemorrhage following Pipeline Embolization Device treatment is a rare-but-devastating complication, with nearly all patients having morbidity or mortality. Variables associated with intraparenchymal hemorrhage included the use of multiple Pipeline Embolization Devices and treatment of ruptured aneurysms. The Shuttle, a device that was previously thought to be associated with intraparenchymal hemorrhage, was not associated with it.

ABBREVIATIONS: IntrePED = International Retrospective Study of the Pipeline Embolization Device; IPH = intraparenchymal hemorrhage; PED = Pipeline Embolization Device
after flow-diverter treatment, and embolization of polyvinylpyrrolidone, a compound found in a number of catheters including the Shuttle guide sheath (Cook, Bloomington, Indiana).10 Using the International Retrospective Study of the Pipeline Embolization Device (IntrePED) registry, we compared the clinical and procedural characteristics of patients who had postoperative IPH and those who did not, to determine which clinical and procedural characteristics were associated with IPH.

MATERIALS AND METHODS

Study Design and Participants

This study is a subanalysis of the IntrePED study, which has been previously published.14 Details regarding ethics committee and institutional review board approval and inclusion and exclusion criteria are provided in the original article.14 Several additional subgroup analyses separate from this study are currently under way by using data from the IntrePED registry. This study will be the only subgroup analysis performed examining variables associated with IPH in the IntrePED registry. We retrospectively evaluated all patients with intracranial aneurysms treated with the Pipeline Embolization Device in the IntrePED registry. Seven hundred ninety-three patients treated for 906 aneurysms were enrolled.

Procedures

Because this was a retrospective registry, procedural details and patient management varied across centers. All centers reported baseline characteristics of patients and aneurysms, procedural information, and follow-up information from clinic visits or telephone calls by using a common study protocol form. Site investigators identified patients who had IPH by using the study protocol form. All complications including IPH were reviewed in detail by an Adverse Events Review Committee, comprising 3 members of the Steering Committee, including the overall study Principal Investigator. The committee determined whether the IPH was major or minor. A “major” adverse event was defined as an ongoing clinical deficit at 7 days following the event. All major adverse events were included in the neurologic morbidity and mortality rates. Timing of all adverse events was in relation to the time of the PED placement.

Baseline Characteristics and Outcomes

For each patient, the following characteristics were collected as part of this study: age, sex, hypertension, control of hypertension, smoking status, aneurysm location, aneurysm rupture status, aneurysm type, aneurysm size, use of antiplatelet medications before the procedure, use of platelet aggregation studies, heparin administration and reversal, number of PEDs used, type of sheath used, type of guidewire used, balloons used, and type of closure device used. The incidence of IPH was calculated for each of the above-mentioned variables.

In addition, for patients with any cerebrovascular hemorrhagic complication, we obtained the following information: whether the hemorrhage was ipsilateral or contralateral to the device; timing after surgery; final clinical outcome (minor morbidity, major morbidity, death); and a clinical report of a preceding embolic event and other procedural complications, including but not limited to vessel perforation. “Minor morbidity” was defined as a clinical deficit that persisted <7 days, and “major morbidity” was defined as a clinical deficit that persisted ≥7 days.

Statistical Analysis

Statistical analyses were performed by using SAS, Version 9.2 or higher (SAS Institute, Cary, North Carolina). Descriptive statistics will be used to present the data and to summarize the results. Discrete variables will be presented by using frequency distributions and cross-tabulations. Continuous variables will be summarized by presenting the number of observations and mean, SD, median, minimum, and maximum values. For categoric variables, differences between the randomized arms were tested by using appropriate contingency table analyses (Exact or \( \chi^2 \) approximations). For continuous variables, the differences were tested by using an unpaired Student \( t \) test or a nonparametric test, depending on variable distribution. Odds ratios and 95% confidence intervals were obtained by using the univariate logistic regression. All statistical analyses were performed on a per-patient basis.

Role of the Funding Source

An academic Principal Investigator and an academic Steering Committee supervised the trial design and operations. The Principal Investigator and Steering Committee were independent of the funding source. The Steering Committee interpreted the results, and the Principal Investigator wrote the report. The study sponsor was responsible for site management, data management, statistical analysis, and safety reporting. The corresponding author had full access to all study data and had final responsibility for the decision to submit for publication.

RESULTS

Patient and Aneurysm Characteristics and IPH

A summary of the baseline characteristics of all patients included in the IntrePED registry is provided elsewhere.14 Twenty (2.5%) patients with 21 treated aneurysms had IPH, while 773 patients (97.5%) did not. There was no difference in the mean age of patients with and without IPH (61.4 ± 13.4 years versus 56.8 ± 14.2 years, \( P = .16 \)). Smoking rates (OR, 1.41; 95% CI, 0.40–4.92; \( P = .59 \)) were not associated with IPH. There was a trend toward higher odds of IPH in the hypertension group (OR, 2.45; 95% CI, 0.96–6.23; \( P = .06 \)). These data are summarized in Table 1.

No aneurysm locations were associated with higher or lower odds of IPH. There was a similar rate of IPH in anterior circulation versus posterior circulation aneurysms (OR, 1.14; 95% CI, 0.26–5.00; \( P = .86 \)). Treatment of ruptured aneurysms was associated with higher odds of IPH (OR, 4.44; 95% CI, 1.65–11.95; \( P = .005 \)). There was no difference in IPH rates by aneurysm type or aneurysm size. These data are summarized in Table 1.

Procedure Characteristics

Use of ≥3 PEDs (OR, 4.10; 95% CI, 1.34–12.58; \( P = .04 \)) was associated with higher odds of IPH. Use of the Shuttle was not associated with higher odds of IPH (OR, 0.95; 95% CI, 0.38–2.45; \( P = .95 \)). Pretreatment antiplatelet therapy (OR, 0.93; 95% CI,
These findings suggest that in addition, other studies from the interventional cardiology literature have demonstrated that multiple PEDs. The use of dual antiplatelet agents has also been proposed as a potential etiology of IPH. In general, patients treated with flow-diversion therapy confirm that approximately 2% of patients will have ipsilateral IPH. All patients who experienced IPH in our study had either major morbidity or mortality. Most IPH cases occurred within the first week of the procedure, and all cases occurred within 6 months of the procedure. In our series, treatment variables associated with IPH included treatment of ruptured aneurysms and the use of ≥3 PEDs. The Shuttle, a device that was previously postulated to be associated with IPH, was not associated with IPH in our study.10,12 These findings suggest that the etiology of IPH following PED treatment is multifactorial, due to a constellation of risk factors, including aneurysm rupture status and the use of multiple PEDs.

The exact mechanism of IPH following PED treatment is uncertain, but a number of different theories have been proposed. One histopathologic study of 3 patients who died after PED-associated intracranial hemorrhage demonstrated that in each case, there was evidence of a foreign material (polyvinylpyrrolidone) in the distal vasculature of the hemorrhagic lesion.10 Polyvinylpyrrolidone is a substance that is commonly used as a coating material for a number of interventional devices, including the Shuttle guide sheath. In that study, the authors demonstrated that macroscopic bits of polyvinylpyrrolidone could be released from this device with minimal manipulation.10 In addition, other studies from the interventional cardiology literature have demonstrated that friction during placement and manipulation of the Shuttle sheath results in deposition of hydrophilic embolic materials causing substantial foreign-body reactions.15–17 Polyvinylpyrrolidone emboli have been shown to result in angiothrombosis and granulomatous angiitis, with resultant vascular injuries.14 However, Hu et al18 did not find any evidence of such granulomatous reaction in association with these polyvinylpyrrolidone emboli following PED treatment. In our current study, we found no association between the Shuttle and IPH following flow-diversion therapy. Given the large size of our study compared with prior studies implicating the Shuttle as causing IPH, our data call into question the association.

### Timing and Clinical Outcomes of IPH

Of the 20 patients who had IPH, 11 (55.0%) had it within 1 week of the procedure. Four patients (20.0%) had IPH between 1 week and 1 month of the procedure, 1 patient had IPH between 1 and 3 months of the procedure (5.0%), and 3 patients had IPH between 3 and 6 months of the procedure (15.0%). No patients had IPH after 6 months following treatment. The median time of onset for IPH was 5 days, the mode was 1 day as 6 patients had IPH 1 day following treatment. In 1 patient, the timing of the IPH was uncertain. Among patients with IPH, 9 (45.0%) died, 10 (50.0%) had major neurologic morbidity, and 1 patient (5.0%) had minor neurologic morbidity. The location of the IPH was ipsilateral to the device in 16 patients (80.0%) and contralateral to the device in 3 patients (15.0%). In 1 patient, the location of the hemorrhage was unknown. Four patients with IPH (20.0%) had a clinical ischemic event (transient ischemic attack or stroke) before the IPH. One patient had IPH the day after the procedure following perforation of a vessel with a guidewire, and 1 patient had IPH with associated SAH resulting from spontaneous rupture of a treated giant cavernous carotid aneurysm.

### DISCUSSION

Our current large, multicenter study of flow-diversion therapy confirms that a number of different theories have been proposed. One histopathologic study of 3 patients who died after PED-associated intracranial hemorrhage demonstrated that in each case, there was evidence of a foreign material (polyvinylpyrrolidone) in the distal vasculature of the hemorrhagic lesion.10 Polyvinylpyrrolidone is a substance that is commonly used as a coating material for a number of interventional devices, including the Shuttle guide sheath. In that study, the authors demonstrated that macroscopic bits of polyvinylpyrrolidone could be released from this device with minimal manipulation.10 In addition, other studies from the interventional cardiology literature have demonstrated that friction during placement and manipulation of the Shuttle sheath results in deposition of hydrophilic embolic materials causing substantial foreign-body reactions.15–17 Polyvinylpyrrolidone emboli have been shown to result in angiothrombosis and granulomatous angiitis, with resultant vascular injuries.14 However, Hu et al18 did not find any evidence of such granulomatous reaction in association with these polyvinylpyrrolidone emboli following PED treatment. In our current study, we found no association between the Shuttle and IPH following flow-diversion therapy. Given the large size of our study compared with prior studies implicating the Shuttle as causing IPH, our data call into question the association.

The use of dual antiplatelet agents has also been proposed as a potential etiology of IPH. In general, patients treated with flow diverters such as the PED are treated with at least 3 months of dual antiplatelet therapy. A number of studies have demonstrated that most IPHs following PED placement occur within 1 month and...
The We did not study the association between How- Similar hemodynamic demonstrated that P2Y12 reaction unit values of units and the risk of hemorrhagic complications have demon- were to be maintained on dual antiplatelet regimens. Studies ex- would be impossible to find a statistical correlation between the platelet therapy coincide cannot be dismissed. In our study, it fact that the timing of these events and the duration of dual anti- therapies for at least 3 months, similar to PED use, so the increased number of reported IPHs among PED patients relative to stent-...
no previous study has to date demonstrated a strong statistical correlation between the use of multiple PEDs and IPH. The association between the use of multiple PEDs and hemorrhagic complications is likely due to multiple factors including prolonged procedural time, increased platelet activation, and possible hemodynamic alterations from the placement of multiple stents.\textsuperscript{19,25}

**Limitations**

Our study has limitations. First, because the number of IPH events was low, we are limited in our power to detect associations between IPH and the above-mentioned variables. Our study protocol did not require regular postoperative imaging with CT or MR imaging. Thus, we cannot determine whether these areas of hemorrhage are due to hemorrhagic transformation of silent infarctions. Another limitation is that for patients receiving platelet testing, we do not have information regarding platelet responsiveness before the hemorrhagic event or whether and how antplatelet prescriptions changed in response to these tests.

Last, we do not have any consistent data regarding how these hemorrhages were managed. A recent study by Tomas et al\textsuperscript{13} demonstrated that surgical evacuation of IPHs following flow-diverter treatment resulted in favorable clinical outcome on follow-up. These procedures were safe and effective in all 4 cases in the Tomas et al study, despite the use of dual antplatelet therapy as all patients had platelet transfusion immediately before the surgical procedure. Single antplatelet therapy with aspirin in the immediate postoperative period was safe and effective in all 4 cases as no patients had rehemorrhage or in-stent thrombosis or stroke.

**CONCLUSIONS**

Spontaneous IPH following endovascular treatment of intracranial aneurysms with the PED is a rare-but-devastating complication with 100% of patients having major morbidity or mortality. The exact cause of this complication is not well-established and is likely multifactorial. Variables associated with IPH include use of multiple PEDs and treatment of ruptured aneurysms. All IPHs occurred within 6 months of the procedures, suggesting that the use of antplatelet therapy is a potential risk factor. The Shuttle, a device that was previously thought to be associated with IPH, was not associated with it in this study. Future efforts for reducing the risk of hemorrhagic complications following PED placement should focus on limiting the number of PEDs used, when possible.
