ABSTRACT

We propose that a nonthermal X-ray arc inside the remnant of Tycho’s supernova (SN) represents the interaction between the SN ejecta and the companion star’s envelope lost in the impact of the explosion. The X-ray emission of the remnant further shows an apparent shadow casted by the arc in the opposite direction of the explosion site, consistent with the blocking of the SN ejecta by the envelope. This scenario supports the single degenerate binary origin of Tycho’s SN. The properties of the X-ray arc, together with the previous detection of the companion candidate and its space velocity by Ruiz-Lapuente et al. and Hernández et al., enable us to further infer that (1) the progenitor binary has a period of 4.9 ± 3.0 days, (2) the companion gained a kick velocity of 42 ± 30 km s⁻¹, and (3) the stripped envelope mass is about 0.0016 (±0.003) M☉. However, we note that the nature of the companion candidate is still under debate, and the above parameters need to be revised according to the actual properties of the companion candidate. Further work to measure the proper motion of the arc and to check the capability of the interaction to emit the amount of X-rays observed from the arc is also needed to validate the current scenario.

Key words: ISM: supernova remnants – supernovae: general – supernovae: individual (Tycho’s Star)

1. INTRODUCTION

While Type Ia supernovae (SNe Ia) play a fundamental role in cosmology and chemical evolution of the universe, their exact origin remains greatly uncertain. One of the leading mechanisms for such an SN is the thermonuclear explosion of a white dwarf when its mass reaches a critical value via accretion from a normal stellar companion in a binary, which is called the single-degenerate scenario (Nomoto 1982; Hillebrandt & Niemeyer 2000). This scenario is due to the merger of two white dwarfs (the double-degenerate scenario; Iben & Tutukov 1984; Whelan & Iben 1973).

2. OBSERVATION AND DATA REDUCTION

Table 1 lists the 12 Chandra observations of the Tycho SNR used in this study. These observations were carried out by the ACIS-I, the imaging array of the Advanced CCD Imaging Spectrometer (ACIS), with a field of view large enough to cover the whole remnant. The data were calibrated with the Chandra Interactive Analysis of Observations (CIAO V4.1) software package following the standard procedure to correct for charge-transfer inefficiency effects and the time dependence of the gain, to clean bad pixels, and to remove time intervals of background flares. The final total effective exposure for these observations is a little bit longer than 1 Ms.

3. RESULTS

Figure 1 shows the intensity images of the remnant in different energy bands. In the 4–6 keV band image (Figure 1(a)), which is dominated by nonthermal X-ray emission sensitive to shocks, which accelerate particles, there appears an intriguing arc (as marked in the figure) only about half way from the SN site (R.A. (2000) = 00:25:23.8; decl. (2000) = 64:08:44.7; Ruiz-Lapuente et al. 2004) and is as bright, narrow, and sharp as those filaments at the outer boundaries of the remnant. This unusual arc was first noticed by Warren et al. (2005). They suggested that it may still be part of the SNR rim seen in projection. In comparison, Figures 1(b), (c), and (d) show the remnant in 1.6–2.0, 2.2–2.6, and 6.2–6.8 keV energy bands, representing the intensity distributions of Si, S, and Fe emission lines, respectively. We find that the Fe Kα line emission is unusually faint in a cone just outside of the arc (in the direction away from the SN site), in comparison with the other regions beyond the same radius. The opening angle of this cone

Observatory (Chandra), this remnant is an ideal laboratory to search for the stripped mass entrained in the ejecta.
Figure 1. ACIS-I intensity images of the Tycho SNR in the (a) 4–6 keV, (b) 1.6–2.0 keV, (c) 2.2–2.6 keV, and (d) 6.2–6.8 keV bands, which represent the nonthermal continuum, Si, S, and Fe emission distributions, respectively. The images have been Gaussian-smoothed with FWHM = 3.5′′ for (a) and 7.4′′ for (b), (c), and (d). The color changes logarithmically from $7.4 \times 10^{-6}$ to $1.5 \times 10^{-4}$ counts cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$ for (a), $1.5 \times 10^{-4}$ to $5.9 \times 10^{-3}$ counts cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$ for (b), $7.4 \times 10^{-3}$ to $1.5 \times 10^{-3}$ counts cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$ for (c), and $2.2 \times 10^{-3}$ to $3.0 \times 10^{-3}$ counts cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$ for (d). The contour levels represent the 4–6 keV emission and correspond to $1.5 \times 10^{-5}$, $3.0 \times 10^{-5}$, $8.9 \times 10^{-5}$, and $1.2 \times 10^{-4}$ counts cm$^{-2}$ s$^{-1}$ arcmin$^{-2}$, respectively. The images are produced from the 12 ACIS-I observations listed in Table 1. The green crosses denote the supernova explosion site inferred from the proper motion of Tycho G (Ruiz-Lapuente et al. 2004); the blue (white) circle defines the inner (outer) boundary of the region from which the azimuth mean brightness profiles in the left (right) panel of Figure 2 were produced.

The spectrum of the arc is shown in Figure 3. The on-source spectrum is extracted from the region defined by the inner polygon in Figure 1(a), while the background is from the region between the inner and outer polygons. Figure 3 shows obvious dips at the positions of the Si, S, and Fe lines in the source spectrum obtained. Since the background thermal emission dominates the nonthermal emission at these energies, these dips are probably due to the clumpy distribution of the SN ejecta and so the highly variable background thermal emission surrounding the arc. Fitting the source spectrum with a power-law model gives a photon index of $2.45 \pm 0.09$ (90% confidence errors), an absorption column density of $(8.7 \pm 0.9) \times 10^{21}$ cm$^{-2}$, an unabsorbed 0.5–10 keV flux of $7.8 \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$, and
χ² of 291 for 200 degrees of freedom. If we ignore the data in 1.6–2.0, 2.2–2.6, and 6.0–7.0 keV, which are probably affected by the oversubtraction of the background line emission, the fitted parameters are then photon index of 2.47±0.08, absorption column of density 9.0±0.5 × 10^{21} cm⁻², and unabsorbed 0.5–10 keV flux of 8.4 × 10⁻¹³ erg cm⁻² s⁻¹, as well as a significantly improved χ² of 176 for 171 degrees of freedom. Therefore, we conclude that the arc is nonthermal.

4. THE NATURE AND ORIGIN OF THE X-RAY ARC

We find that the X-ray arc is most probably in the interior of the SNR instead of a (morphologically) unusual feature of the outer rim projected well inside the remnant. The sharp and bright appearance of the X-ray arc is similar to those of the filaments at the outer rim of the SNR (Cassam-Chenaï et al. 2007), implying that the arc is observed almost edge-on. If it is in the outer layer of the SNR and the observed small angular distance from the geometric center is due to the projection effect, then the arc should be much more diffuse as it is observed half face-on. In the 4–6 keV map, there exist some relatively bright features within the blast wave boundary. However, most of them are substantially more diffuse and coincide with bright thermal structures spatially, and none of them is as far away from the boundary as the arc is (see also Warren et al. 2005). The arc is convolved toward the SN site, which is opposite to those of the filaments at the outer boundary. Furthermore, larger and fainter filaments tend to run northward from the southeast (Warren et al. 2005) and bend outward. The morphology of the arc can be naturally produced by the interaction between the SN ejecta and a cloud. As will be discussed in the following, the arc most probably represents the materials stripped from the companion star by the SN explosion and is in the interior of the SNR.

First, the arc must be related to the progenitor system of the SN. If it is not related to the progenitor system, it should then represent a dense cold molecular cloud that has survived for a long time. Actually, the millimeter and optical observations suggest that the Tycho SNR is possibly interacting with molecular clouds at the northeastern and the southwestern rims (Lee et al. 2004; Ghavamian et al. 2000). These regions show strong 4–6 keV emission. However, neither CO nor optical emission enhancement has been detected to be spatially coincident with the X-ray arc. It is unlikely to be a molecular cloud.

Second, the arc cannot arise from the materials ejected by the progenitor binary system of the SN. Since the mass donor is suggested to be very similar to the Sun though a slightly evolved one (Ruiz-Lapuente et al. 2004), we do not expect that it could contribute to the cloud (e.g., via a stellar wind). One might think that a planetary nebula surrounding the exploded white dwarf could be a source of the cloud material. However, planetary nebulae always show a spherically or axially symmetric morphology. The singleness of the X-ray arc makes this possibility very unlikely.

Finally, and most probably, the matter generating the X-ray arc is stripped from the companion star during the SN explosion. Such a mechanism has been suggested by many theoretical works (Wheeler et al. 1975; Fryxell & Arnett 1981; Taam & Fryxell 1984; Chugai 1986; Marietta et al. 2000; Meng et al. 2007) although no direct observational evidence is currently available (Leonard 2007). Arguments for this mechanism are as follows: (1) the stripped materials are confined in a small angular range, which can naturally explain the singleness of the arc; (2) the opening angle (about 20°) of the arc relative to the SN site (Ruiz-Lapuente et al. 2004), the absence of the X-ray line emission in the cone away from the arc, and the local enhancements of X-ray emission immediately within the arc radius are all well consistent with the ejecta blocking scenario of the stripped stellar envelope (Marietta et al. 2000); (3) the gas in the envelope of the companion star is expected to have a temperature of a few 10⁴ K; it cannot cool down to the CO emitting temperature in 400 years, especially in a hot environment; (4) the impact of the SN blast wave and ejecta on the stripped envelope will generate a shock wave, just like those represented by the nonthermal X-ray filaments at the outer rim, but with a smaller velocity because the envelope is denser than the surrounding interstellar medium (ISM). The shock wave can accelerate electrons to emit the nonthermal X-rays; and (5) the angle between the direction of the arc to the explosive center...
Figure 3. Chandra ACIS spectrum of the X-ray arc, together with a power-law model fit as described in the text. In the spectral analysis, the background extracted from a region immediately surrounding the X-ray arc has been subtracted.

![Diagram](Image)

Figure 4. Illustration of the progenitor binary and the impact of the SN on the companion star. The companion star gained a kick in addition to the original orbital motion. Therefore, the angle between the kick direction and the companion star. The companion star gained a kick in addition to the proper motion velocity of Tycho G is well consistent with the theoretical predictions and simulations (Marietta et al. 2000; Meng et al. 2007). For Tycho G, the measured radial velocity is $-50 \pm 10$ km s$^{-1}$ (with the projected Galactic rotation contribution $-30 \pm 10$ km s$^{-1}$ subtracted; Hernández et al. 2009), while the tangential one is $-94 \pm 27$ km s$^{-1}$ (Ruiz-Lapuente et al. 2004). Taking the uncertainty in the distance ($3 \pm 1$ kpc; de Vaucouleurs 1985; Hernández et al. 2009) into account, the tangential velocity is $-94 \pm 41$ km s$^{-1}$. The projected angle between the stripping direction and the current velocity of Tycho G relative to the SN site is $\alpha = 63^\circ \pm 13^\circ$, where the error accounts for the uncertainties in both the proper motion measurement and the arc/shadow central line (about $2^\circ$). Because the X-ray arc/shadow is viewed almost edge-on (with an assumed uncertainty of $10^\circ$), the stripped velocity should be nearly perpendicular to the line of sight. Therefore, the real angle between the stripping (or the kick) and the velocity of Tycho G is $\beta = 67^\circ \pm 16^\circ$. Numerical simulation by Marietta et al. (2000) shows that the ratio between the orbital velocity and kick velocity is from 2.3 to 11.2, and so the real angle between the kick and the space velocity of the stellar remnant is between $67^\circ$ and $85^\circ$. Our result is consistent with these predictions.

We can then infer that the companion had an orbital velocity ($V_o$) of $98 \pm 36$ km s$^{-1}$ in the progenitor binary, received a kick velocity ($v_k$) of $42 \pm 30$ km s$^{-1}$, and the inclination angle of the orbital plane is $31^\circ \pm 13^\circ$. We can also constrain the separation between the two stars in the progenitor binary with the formula $a = \frac{M^2 G}{(M_1 M_2 V_o^2)}$, where $M_1$ is the mass of the SN progenitor and is assumed to be 1.4 solar mass—the Chandrasekhar mass of a white dwarf, $M_2$ is the mass of the companion star, and $G$ is the gravitational constant. Tycho G is similar to the Sun spectroscopically (Ruiz-Lapuente et al. 2004; Hernández et al. 2009) and thus has a mass of about one solar or slightly higher (depending on the luminosity type; see below). We then estimate $a = \frac{1}{\pi^2} (2.7 \pm 2.0) \times 10^7$ km, where $\epsilon$ is the mass stripped from the companion and should be considerably smaller than one, hence negligible. The corresponding orbital period is then $4.9^{+5.5}_{-3.0}$ days. These orbital parameters and kick velocity are summarized in Table 2. They are well consistent with the theoretical predictions (Marietta et al. 2000; Meng et al. 2007). Pakmor et al. (2008) simulated the impact of Type Ia SN on main-sequence binary companions. They find that the kick velocity of the companion star after the impact of the SN be in a circular orbit just before the SN (Marietta et al. 2000; Meng et al. 2007). The above interpretation together with the existing measurement of the companion’s present velocity gives tight constraints on properties of the progenitor binary of the Tycho SN (see Figure 4 for an illustration). Because of the SN impact, the companion star should receive a kick as well as the envelope stripping in the same direction and in the orbital plane of the progenitor binary. The direction should be perpendicular to the orbiting velocity of the companion as it is expected to

5. CONSTRAINTS ON THE PROGENITOR BINARY SYSTEM

The above interpretation together with the existing measurement of the companion’s present velocity gives tight constraints on properties of the progenitor binary of the Tycho SN (see Figure 4 for an illustration). Because of the SN impact, the companion star should receive a kick as well as the envelope stripping in the same direction and in the orbital plane of the progenitor binary. The direction should be perpendicular to the orbiting velocity of the companion as it is expected to

Notes. The velocity and mass values of Ruiz-Lapuente04 were taken from Ruiz-Lapuente et al. (2004) and Hernán\’dez et al. (2009), and those of Kerzendorf09 were from Kerzendorf et al. (2009). The uncertainties of all the adopted and derived parameters in this table are at 1σ confidence level.

The angular size (about 20\(^\circ\)) of the X-ray arc relative to the SN site is smaller than that subtended by the Roche lobe (40\(^\circ\)), which may be expected from the compression and stripping of the envelope in the bow-shocked SN ejecta material (Figure 4). The angular separation between the SN site and the arc is about half of the outer radius of the remnant, which presumably reflects the difference in their velocities. A Type Ia SN explosion releases a typical kinetic energy of (1–1.4) $\times 10^{51}$ erg, and the mean ejecta velocity ($v_{ej}$) for a Chandrasekhar mass of 1.4 M\(_{\odot}\) is 8500–10,000 km s\(^{-1}\). The momentum conservation for the stripped mass (M\(_{ej}\)), the kick companion star, and the ejecta in the solid angle subtended by the envelope can be expressed as $M_{ej}v_{ej} = (M_{ej} + M_{cw})\frac{v_{cw}}{2} + M_{ej}v_{k}$. Assuming a spherically symmetric SN and using a companion star mass of 1 solar, an ejecta velocity of 9230 km s\(^{-1}\), and $v_{k} = 42$ km s\(^{-1}\), as well as the 20\(^\circ\) wide solid angle, we estimate the mass of the envelope to be 0.0016 M\(_{\odot}\). Taking the uncertainty of $v_{k}$ (±30 km s\(^{-1}\)) into account, the upper limit of the stripped mass is 0.0083 M\(_{\odot}\). The mass outside the assumed solid angle (e.g., to account for the full Roche lobe) should be negligible because of the expected highly concentrated radial mass profile of a giant star (Meng et al. 2007). This estimation of the stripped mass is consistent with that observed for two extragalactic SNe Ia (Leonard 2007), significantly lower than the theoretical predictions by Marietta et al. (2000) and Meng et al. (2007), and is close to (though still lower than) 1 to several percent that simulated by Pakmor et al. (2008).

Although the stripped mass is small, it is enough to produce the X-ray arc. Katsuda et al. (2010) estimated that the mean ambient density of Tycho’s SNR is 0.0015 cm\(^{-3}\), or <0.2 cm\(^{-3}\). The mass of the ambient ISM in a cone of 20° radius should then be about 4 $\times 10^{-5}$ M\(_{\odot}\), or < 5 $\times 10^{-5}$ M\(_{\odot}\), smaller than or at most comparable to the stripped mass. Since bright nonthermal filaments have been observed all along the rim of the remnant (e.g., Cassam-Chenái et al. 2007), the interaction between SN ejecta (probably denser at the arc position) and the stripped mass should be strong enough to be responsible for the X-ray arc emission.

Recently, Kerzendorf et al. (2009) have reported the new space velocity and mass measurements of Tycho G, which are different from those by Ruiz-Lapuente et al. (2004). We list the new measurements and the corresponding binary parameters in Table 2. The new orbital radius and period are several times those derived from Ruiz-Lapuente et al. (2004) and Hernán\’dez et al. (2009). The angle between the kick and the space velocity of the stellar remnant is therefore about 82°, only marginally consistent with the numerical simulations (Marietta et al. 2000). In the scheme of momentum conservation, the amount of the stripped mass is derived as 0.0087 ± 0.0017 M\(_{\odot}\). It is higher than that from Ruiz-Lapuente et al. (2004) and Hernán\’dez et al. (2009), but still consistent with the simulations by Pakmor et al. (2008) and the observations by Leonard (2007).

As pointed out by Kerzendorf et al. (2009), there is a simple relationship between the companion’s rotation velocity ($v_{rot}$) and its orbital velocity ($v_{orb,2}$): $v_{rot} = \frac{M_{ej}M_{2}}{M_{ej} + M_{2}} f(q) v_{orb,2}$, where $f(q)$ is the ratio of the companion’s Roche lobe radius to the orbital separation and $q = M_1/M_2$ is the mass ratio of the primary to the companion at the time of the explosion. If $M_2$ is 0.3–0.5 M\(_{\odot}\) (Kerzendorf et al. 2009), $v_{rot}$ of the companion’s surface should be about 24 km s\(^{-1}\), much higher than 7.5 km s\(^{-1}\), the upper limit of Tycho G’s rotation velocity ($v_{rot,\sin i}$), where $i$ is the inclination angle of the orbital velocity. Using the inclination angle that we obtained in this paper, the upper limit of $v_{rot}$ for Tycho G is about 10 km s\(^{-1}\), still significantly lower than 24 km s\(^{-1}\). Kerzendorf et al. (2009) proposed that a red giant scenario where the envelope’s bloating has significantly decreased the rotation could be consistent with their observation of the low rotation velocity. Since the effect of the inclination angle is small, Tycho G remains a stripped giant if it is the mass donor, as suggested by Kerzendorf et al. (2009).

If the companion is about 1 M\(_{\odot}\), its surface velocity was about 60 km s\(^{-1}\) at the SN explosion, as derived from the binary parameters listed in Table 2 and that it filled the Roche lobe, which has a radius of about 5.7 R\(_{\odot}\). However, the companion may have a radius of 1–3 R\(_{\odot}\) now (Ruiz-Lapuente et al. 2004; Hernán\’dez et al. 2009), and so the surface velocity of the stellar remnant should be about 10–31 km s\(^{-1}\), marginally consistent with the upper limit of $v_{rot}$ observed by Kerzendorf et al. (2009) and the inclination angle that we obtained. We speculate that the decrease in the radius is possibly due to the destruction of the white dwarf. Before the SN explosion, the strong radiation of the accreting white dwarf inflated the envelope of the companion star to fill the Roche lobe, and the radius of the companion star shrinks to 1–3 R\(_{\odot}\) now because the heating of the white dwarf does not exist. In addition, we note here that the shrinkage did not accelerate the rotation significantly because the inflated envelope only contributes a small fraction of the total mass of the companion star and most of it was stripped away by the SN.

Using the position of the arc and the age of the remnant, we obtained a mean velocity of the arc outward from the SN site to be about 0.28 yr\(^{-1}\). As measured by Katsuda et al. (2010), the Tycho’s remnant is expanding at a proper motion velocity around 0.3 yr\(^{-1}\), in contrast to the mean expansion speed of about 0.55 yr\(^{-1}\) from the radius and age of the remnant. This shows that the remnant is in a deceleration phase due to the interaction with the ISM. If the arc is a projected feature that is in the outer
layer of the remnant, it should have a proper motion velocity of \(\sim 0.15 \text{yr}^{-1}\). If the arc is actually about half way from the SN site and represents the interaction of the SN explosion and the stripped companion envelope, the proper motion should be quite close to the mean velocity \(\sim 0.28 \text{yr}^{-1}\), as discussed below.

On one hand, the arc is unlikely in an accelerating phase. The binary separation is tiny compared to the distance of the X-ray arc from the SN site. Even the Fe ejecta, which is expected to have the lowest velocity and was measured as \(\sim 3000 \text{km s}^{-1}\) currently (Furuzawa et al. 2009), can pass such a separation within several hours. Most of the impact of the ejecta on the companion envelope (and thus the acceleration of the stripped mass) should take place soon after the explosion. On the other hand, the arc cannot be significantly decelerated. Since the distance of the X-ray arc from the SN site is about half of the remnant radius, using the ISM density given by Katsuda et al. (2010), the ISM mass in the cone between the SN site and the X-ray arc is \(\sim 5 \times 10^{-6} M_\odot\), much smaller than the stripped envelope mass. Although the ISM decelerates the motion of the stripped envelope material, it is quite insignificant given the small mass. Therefore, the stripped envelope went through a very short accelerating phase in the beginning of the SN explosion and has remained in an almost free expansion state since then.

We have attempted to measure the proper motion of the X-ray arc so as to check the above scenario, since the expected proper motion may be detectable at *Chandra*’s resolution. Unfortunately, the arc has typically fallen more or less at a gap between two ACIS-I chips, especially in three early observations. In addition, the arc is heavily contaminated by strong thermal emission in the low energy band. In 4–6 keV, where nonthermal emission dominates, the counting statistics of the arc are typically not sufficient in early observations. As a result, we cannot yet get a reliable multi-epoch measurements of the arc positions to allow for a reliable determination of the proper motion. Future observations with more careful positioning of the arc in the detector and with a total exposure time comparable to the ACIS-I observations in 2009 will make such measurements feasible.

6. SUMMARY

We have shown that a self-consistent single-degenerate binary model provides a natural and unified interpretation of the observed unique X-ray arc/shadow in Tycho’s SNR. Two sets of parameters of the progenitor binary system have also been presented using the optical observation results of the candidate companion star (Tycho G) obtained by Ruiz-Lapuente et al. (2004) and Kerzendorf et al. (2009). The main points in favor of our interpretation are: (1) although the nonthermal X-ray arc is halfway from the remnant center, the high brightness shows that it is viewed almost edge-on and so unlikely to be a projected feature in the outer layer of the remnant. Together with its sharp inward convex shape, the arc most probably represents the interaction between the ejecta and a bulk of materials in the interior of the remnant. (2) This bulk of materials cannot be due to a pre-existing molecular cloud or materials ejected by the progenitor binary system. The impact generating the X-ray arc is most likely between SN ejecta and the stripped envelope of the companion star. (3) The X-ray emission of the remnant shows an apparent shadow casted by the arc in the opposite direction of the explosion site, and there are local enhancements in the same direction immediately within the X-ray arc, consistent with the blocking of the SN ejecta by the envelope. (4) We obtained a stripped mass of \(\leq 0.0083 M_\odot\), which is consistent with that observed for two extragalactic SNe Ia (Leonard 2007) and close to the recent simulations by Pakmor et al. (2008).

(5) The angle between the motion of the companion candidate and the direction of the arc as well as the derived kick velocity of the companion star is well consistent with the theoretical predictions and the numerical simulation results.

However, we note that there are still several points that cannot be interpreted well by the current scenario, and further work is needed to reveal the physical processes related to the nonthermal X-ray arc. (1) The properties of Tycho G and whether it is the stellar remnant of Tycho’s SN are under debate (Ruiz-Lapuente et al. 2004; Hernández et al. 2009; Kerzendorf et al. 2009). If Tycho G is not the stellar remnant, the binary parameters and kick velocity obtained in this paper are no longer reliable. Also, if Tycho G is the stellar remnant but has properties as obtained by Kerzendorf et al. (2009), the obtained angle between the kick and the space velocity of the stellar remnant is only marginally consistent with the numerical simulations (Marietta et al. 2000). (2) It has not been quantitatively estimated whether the interaction between the stripped envelope and the ejecta can produce shock waves strong enough to produce the nonthermal X-ray arc. (3) We failed to obtain a precise proper motion of the X-ray arc, which is an important criterion to differentiate the X-ray arc as inside the remnant from a projected feature in the outer layer. Further studies of the stellar remnant as well as the measurement of the proper motion velocity of the X-ray arc are therefore urged to check the validity of the scenario proposed in this paper.

We thank the referee for many insightful comments and suggestions that helped us greatly in the revision of the paper. This work is supported by National Basic Research Program of China (973 program, 2009CB824800) and by National Science Foundation of China (10533020 and 10903007).
