Motivated by recent transport measurements on the candidate spin-liquid phase of the organic triangular lattice insulator EtMe₃Sb[Pd(dmit)₂]₂, we perform a controlled calculation of the thermal conductivity at intermediate temperatures in a spin liquid system where a spinon Fermi surface is coupled to a U(1) gauge field. The present computation builds upon the double expansion approach developed by Mross et al. [Phys. Rev. B 82, 045121 (2010)] for small $\epsilon = z_0 - 2$ (where $z_0$ is the dynamical critical exponent of the gauge field) and large number of fermionic species $N$. Using the so-called memory matrix formalism that most crucially does not assume the existence of well-defined quasiparticles at low energies in the system, we calculate the temperature dependence of the thermal conductivity $\kappa$ of this model due to non-critical Umklapp scattering of the spinons for a finite $N$ and small $\epsilon$. Then we discuss the physical implications of such theoretical result in connection with the experimental data available in the literature.

In the last few years, there has been immense experimental progress in unveiling the nature of promising quantum spin liquid (QSL) phases displayed by some insulating materials featuring a two-dimensional (2D) Heisenberg triangular lattice, such as, the organic compounds $\kappa$-(BEDT-TTF)$_2$-Cu$_2$(CN)$_3$ [1, 2] and EtMe₃Sb[Pd(dmit)$_2$]$_2$ (or simply dmit-131) [3–5]. Moreover, in the case of dmit-131, despite the fact that it is clearly a charge insulator, a “Fermi-liquid”-like low-temperature behavior has been observed in both the static susceptibility which remains finite down to the lowest temperatures measured [6] and the specific heat which becomes linear in $T = 20$ mK [5]. Moreover, in the case of dmit-131, despite the fact that it is clearly a charge insulator, a “Fermi-liquid”-like low-temperature behavior has been observed in both the static susceptibility which remains finite down to the lowest temperatures measured [6] and the specific heat which becomes linear in $T = 20$ mK [5]. Moreover, in the case of dmit-131, despite the fact that it is clearly a charge insulator, a “Fermi-liquid”-like low-temperature behavior has been observed in both the static susceptibility which remains finite down to the lowest temperatures measured [6] and the specific heat which becomes linear in $T = 20$ mK [5]. In the present work, the phenomenological description of the spinon Fermi surface is considered in the context of a two-parameter model consisting of fermion fields $(s = \pm)$ with momenta close to two antipodal patches on the spinon Fermi surface interacting with a gauge field. The fermionic momenta are measured locally with respect to the Brillouin zone, which would be small in this case. A conduction mechanism to be effective at intermediate temperatures, since the “gap” between the Fermi surface and the edges of the Brillouin zone would be small in this case. The parameter $\eta$ should scale as $\eta \rightarrow b^{(\epsilon-3)/2} \eta'$ and therefore, for small $\epsilon$, it is always irrelevant in the RG sense. The parameter $\eta$ is dimensionless exactly at $\omega = 2$ (i.e., marginal for this case) and becomes the least irrelevant term for $2 < \omega \leq 3$. As a result, the ratio $(\eta'/\eta)$ always flows to zero for small $\epsilon$ under the RG scaling. This means that the timescales for the spinons are actually longer than for the gauge bosons near the IR fixed point in this limit. This could suggest that the gauge bosons can be assumed, to a first approximation, to be in local thermal equilibrium (i.e., the drag mechanism is a parametrically smaller effect in the system). The timescale for the spinons is actually shorter than for the gauge bosons near the IR fixed point, which is accessible perturbatively for finite $N$. We define $k_x$ and $k_y$, respectively, as the normal and parallel components to the Fermi surface.

As will become clear shortly, the memory matrix can be viewed as a generalization of the concept of scattering rate in Boltzmann theory applicable to systems in which this quantity is not well-defined. Because of this appealing feature, the Mori-Zwanzig approach has been successfully applied to one-dimensional interacting electrons [22] and, in recent years, also to some higher dimensional systems at quantum criticality [23-30]. In this formalism, only the operators with the longest relaxation timescales can potentially contribute to the thermal conductivity of the system, since operators with short-time decay are in general irrelevant in the low-energy effective description. For this reason, these latter operators are not expected to play a key role in the calculation of the transport coefficients in the present model.

Since the action $S$ is invariant under both space translation and global $U(1)$ symmetry, by following Noether’s theorem one finds that both the classical momentum and particle current densities are conserved. These quantities at the quantum level will play a central role in our discussion, since one expects that their corresponding operators should have the longest relaxation timescales.
in the system and, for this reason, we will argue that they dominate the thermal conductivity. Accordingly, we shall write down the translation operator $P_T$ in the system and the current operator $J$, respectively, as follows: 

$$P_T = (P_T^x, P_T^y) = i\eta \int d^2x \sum_{s} \nabla \psi_{s \sigma}^{\dagger} \psi_{s \sigma} + 2\eta (i\partial_\phi \nabla \phi \partial_\phi) \psi_{s \sigma}$$ 

and 

$$J = (J_x, J_y),$$ 

where $J_x = \int d^2x \sum_{s} s \psi_{s \sigma}^{\dagger} \psi_{s \sigma}$ and $J_y = i \sum_{s} \psi_{s \sigma}^{\dagger} (\partial_y \psi_{s \sigma} - \psi_{s \sigma} \partial_y \phi)$ (see, e.g., Ref. [26] for a definition of the same physical quantities in the context of a one-dimensional (1D) model). If all energies are measured with respect to the chemical potential, the Hamiltonian density $h(x)$ of the model is the heat density. Therefore, using the continuity equation for the heat flow $h(x) + \nabla \cdot J = 0$ (where the dot stands for a time derivative), we can also formally obtain the thermal current operator $J_Q = (J_Q^x, J_Q^y)$, whose components are given by

$$J_Q^x = - \int d^2x \sum_{s} \frac{i\eta}{2} (\psi_{s \sigma}^{\dagger} \psi_{s \sigma} - \psi_{s \sigma})$$

and

$$J_Q^y = - \int d^2x \sum_{s} \frac{i\eta}{2} (\psi_{s \sigma}^{\dagger} \psi_{s \sigma}) - (\partial_y \phi)^{\ast} \psi_{s \sigma}.$$ 

To calculate the thermal conductivity of this model, it is important to include all the conserved (or nearly conserved) quantities in the system that have a finite overlap with the above thermal current operator.

To begin with and to set up our notation, we define a matrix of generalized conductivities in the following way

$$\sigma(\omega, T) = \frac{\frac{i}{\omega} \hat{\chi}(T)}{\omega + iM(\omega, T) \hat{\chi}^{-1}(T)}.$$ 

where $\hat{\chi}(T) = \chi(0, T)$ is the matrix of static retarded susceptibilities of some possible “slowly-varying” operators $A$ and $B$ in the system. This matrix of susceptibilities is defined in the conventional way by

$$\hat{\chi}^{AB}(i\omega, T) = \int_0^{1/T} d\tau e^{i\omega \tau} \langle T_{\tau} A^{\dagger} B(0) \rangle,$$

where $\hat{\chi}^{AB}(\omega) = \hat{\chi}^{AB}(i\omega \rightarrow \omega + i0^+)$, the statistical average $\langle \ldots \rangle$ is taken over the grand canonical ensemble, and the volume $V$ has been set to unity. The memory matrix is then given by [24]

$$M_{AB}(\omega, T) = \int_0^{1/T} d\tau \langle \hat{A}^{\dagger}(0) Q \frac{i}{\omega - QLQ} \hat{B}(i\tau) \rangle.$$ 

Here the “super”-operator $L$ is the Liouville operator which is defined as $LA = [H, A] = -i\hat{A}$, where $H$ is the Hamiltonian, and $Q$ projects onto the space of operators perpendicular to all the slowly-varying operators $\{A, B, \ldots\}$. Here we have assumed that the slowly-varying operators in the model have the same signature under time reversal symmetry. The memory matrix encodes the mechanism of relaxation of all the nearly conserved quantities in the system. Due to the projector operator $Q$, this matrix is expected to be also a smooth function of the coupling constant $\eta$ of the model and, for this reason, it can be evaluated in a perturbative way.

Consider first the slowly-varying operators in the present system which are given by $\{O_i\} = \{P_T, J\}$. By analyzing their equations of motion, we obtain that

$$i\hat{P}_T = [P_T, H] = \sum_{s} \eta_s \int d^2x \psi_{s \sigma}^{\dagger} \psi_{s \sigma} \eta (\nabla a + iK a)$$

$$- \eta'(\nabla a) e^{iK x} + \ldots,$$ 

$$i\hat{J}_x = [J_x, H] = 0,$$ 

$$i\hat{J}_y = [J_y, H] = \sum_{s} \eta_s \int d^2x \psi_{s \sigma}^{\dagger} \psi_{s \sigma} (\partial_y a + iK_y a_y)$$

$$\times e^{iK x} + \ldots,$$

where the ellipses represent similar terms (but with no $K$ contribution) generated by the normal part of the interaction between the spinons and the gauge bosons. At this point, it is instructive to pause for a moment in order to analyze separately the contributions arising from the $\eta$ and $\eta'$ terms. This is related to the discussion concerning a possible existence (or non-existence) of the drag effect played by the gauge bosons in the present system. Since the bosons and spinons are weakly interacting in the limit of small $\epsilon$ and finite $N$, it is in principle not clear whether they are able to exchange momentum efficiently in such a case. This discussion is complicated by the fact that in real materials there are always impurities or lattice defects – which were not included in the present analysis – that turn out to be quite effective in destroying the excess momentum of the bosons, while having a negligible effect on the fermions [31, 32]. In that case, the thermal conductivity of the spinons should follow a power-law dependence that would have strong analogies to Bloch’s law for the electron-phonon scattering in metals. In other words, it is indeed possible that the drag effect is masked by the scattering due to the above additional ingredients [31, 32] and therefore we may assume,
to a good approximation, that the gauge bosons are kept in equilibrium. For this regime, we must set \( \eta' \) to zero, since this is the most irrelevant contribution near the IR nontrivial fixed point, as explained before in the present paper. This scenario will be analyzed in some detail below. On the other hand, for samples of extremely high purity, the extrinsic mechanisms mentioned above cannot be invoked any longer. In such a case, the drag effect of the gauge bosons would be important in the system and, for this regime, we must set \( \eta = \eta' \) in Eqs. (9), (10) and (11). We will also analyze the impact of this drag effect on our results concerning the thermal conductivity of the present system.

Given the above discussion, let us assume henceforth the first scenario in which there is no drag effect of the gauge bosons in the system. Later on, we will also examine the second scenario. The thermal conductivity can be formally written \( [33] \) as

\[
\kappa = \frac{1}{T} \sum_{i,j} \chi_{i,j}(T) M_{i,j}^{-1}(T) \chi_{i,j}(T).
\]

(12)

From Eq. (10) it appears at first sight that, since \( J_x \) does not relax in the present model, the inverse of the memory matrix defined by Eq. (8) might display a divergence in our calculation, which would require invoking some extrinsic mechanism (i.e. not included in the present model) such as coupling to disorder, and phonons. Despite this remark, we point out that in fact the operator \( \mathbf{J} \) will not contribute in an effective way to the thermal conductivity in the present model, since its \( x \)-component \( J_x \) has no overlap with the thermal current operator (and its \( y \)-component is, up to a prefactor, equal to \( y \)-component of \( \mathbf{P}_T \) for \( \eta' = 0 \)). In other words, in the limit of finite \( N \) and small \( \epsilon \), the susceptibility \( \chi_{q_{x},q_{y}}(T) \) (for \( q = 0 \)) given by the integral

\[
\chi_{q_{x},q_{y}}(T) = T \sum_{s,a} \int \frac{d^2k}{(2\pi)^2} \frac{1}{\lambda N} \text{sgn}(\omega_n) |\omega_n| \frac{1}{\varepsilon_{k,s} - \varepsilon_{k,s}}
\]

\[
\times \frac{(\omega_n + q_{0}/2)}{\lambda N} \text{sgn}(\omega_n) |\omega_n + q_{0}| \frac{1}{\varepsilon_{k,s} - \varepsilon_{k,s}}
\]

(13)

vanishes identically for any temperature \( T \), i.e. \( \chi_{q_{x},q_{y}}(T) = 0 \) (see Fig. 2(a) for a representation of the corresponding Feynman diagram in this calculation). The above integral can be computed straightforwardly by using Cauchy’s residue theorem and choosing a contour of integration that avoids crossing two branch cuts that exist in the complex plane.

In an analogous way, we can calculate the susceptibility \( \chi_{p_{x},p_{y}}(T) \) in the limit of finite \( N \) and small \( \epsilon \). Since \( \eta \) will cancel out in the final result for the thermal conductivity, we set from this point on \( \eta = 1 \) without loss of generality. In this case, we obtain

\[
\chi_{p_{x},p_{y}}(T) = \frac{4i}{\lambda N} \sum_{s,a} \int \frac{d^2k}{(2\pi)^2} \frac{1}{\varepsilon_{k,s} k_x} \int f(\epsilon) e^{i |\varepsilon_{k,s} k_x|} e^{i \varepsilon_{k,s} T},
\]

(14)

where \( \int_{k_x} = \int \frac{d^2k}{(2\pi)^2} \), \( \int_{\varepsilon} = \int \frac{d\varepsilon}{2\pi} \) and \( f(\epsilon) = [1 + e^{i \varepsilon - T}]^{-1} \) is the Fermi-Dirac distribution. It can be useful to rewrite the above integral in terms of the following dimensionless variables: \( \bar{x} = \beta^{1/2} z_{k_x} \), \( \bar{y} = \beta^{1/2} z_{k_y} \), and \( \bar{z} = \beta \varepsilon \), where \( \beta = 1/T \). As a result, we obtain that this susceptibility scales as \( \chi_{p_{x},p_{y}}(T) = C_s^{(1)}(\lambda N) T^{5/2 - \epsilon/4} \), where the prefactor \( C_s^{(1)}(\lambda N) \) is independent of \( T \) and is finite for small \( \epsilon \) and finite \( N \). We perform a similar calculation for \( \chi_{p_{x},p_{y}}(T) \) and obtain that this quantity also has the same temperature dependence as \( \chi_{p_{x},p_{y}}(T) \), i.e. \( \chi_{p_{x},p_{y}}(T) = C_s^{(2)}(\lambda N) T^{5/2 - \epsilon/4} \), but with a different temperature-independent prefactor \( C_s^{(2)}(\lambda N) \). One may then conclude from this analysis that the translation operator of spinons \( \mathbf{P}_T \) will play the role of only slowly-varying operator in the thermal conductivity calculation for the present system. Therefore, Eq. (12) can be further simplified to

\[
\kappa = \frac{1}{T} \sum_{i,j=x,y} \chi_{i,j}(T) \mathbf{P}_T^{-1} \mathbf{P}_T \chi_{i,j}(T).
\]

(15)

Next, we proceed to calculate the memory matrix operator \( \mathbf{M}_{\mathbf{P}_T} \) for the present model in a controlled way in the same limit as explained before. We note that \( \mathbf{P}_T \) is of order linear in the coupling constant \( g \). Therefore, from Eq. (9), the dominant contribution to \( M \) is of order \( O(g^2) \). Since we want to keep only the leading order contribution to this quantity, we should set the Liouville operator \( L = L_0 + g L_{int} \) to its noninteracting value \( (L \approx L_0) \). In addition, following the same strategy, the grand-canonical average with the full Hamiltonian of the system must be also replaced by the corresponding average in the noninteracting limit, i.e. \( \langle \ldots \rangle_0 \). Lastly, since \( L_0 \mathbf{P}_T = 0 \) \( (i = x, y) \), it can be shown that there is no contribution from the projection operator \( Q \) in the present case, i.e. \( L_0 \mathbf{Q} = L_0 \mathbf{P}_T = L_0 \mathbf{P}_T \) (see, e.g., Ref. [20] for the same condition employed in the context of a 1D model). Therefore, the memory matrix for the present \( U(1) \) spin-liquid model becomes

\[
\mathbf{M}_{\mathbf{P}_T} (\omega \rightarrow 0, T) \approx \lim_{\omega \rightarrow 0} \frac{\langle \mathbf{P}_T; \mathbf{P}_T^0 \rangle - \langle \mathbf{P}_T; \mathbf{P}_T^0 \rangle_0}{\omega} = -i \frac{\partial}{\partial \omega} \langle \mathbf{P}_T; \mathbf{P}_T^0 \rangle_0 \big|_{\omega = 0},
\]

(16)

where \( \langle \mathbf{P}_T; \mathbf{P}_T^0 \rangle_0 = \langle \mathbf{P}_T(\omega) \mathbf{P}_T^0(-\omega) \rangle_0 \). Let us concentrate first on the term \( \langle \mathbf{P}_T; \mathbf{P}_T^0 \rangle_0 \).
Using Wick’s theorem (see Fig. 2(b) for a representation of the corresponding Feynman diagram), its leading term is given by

\begin{equation}
\langle \hat{P}_T^x(\omega) \hat{P}_T^x(-\omega) \rangle_0 = -T^2 \sum_{x,\alpha \atop k_\alpha, k'_\alpha} g^2 \int_{k, k'} G_f^{(x)}(k' + K, k_\alpha) \\
\times G_f^{(x)}(k, k_\alpha) D_b(k' - k, k'_\alpha - k_\alpha + \omega)(k'_x - k_x)^2 + \ldots, \tag{17}
\end{equation}

where the ellipsis refers to the subleading terms. Using Cauchy’s residue theorem with a choice of contour of integration that circumvents crossing a branch cut that exists in the complex plane, the leading term of Eq. 17 can be written as

\begin{equation}
\langle \hat{P}_T^x(\omega) \hat{P}_T^x(-\omega) \rangle_0 = \frac{4}{\lambda^2 N^2} \sum_{x,\alpha} g^2 \int_{k, k'} \int_{\varepsilon, \varepsilon'} \frac{f(\varepsilon)f(\varepsilon')}{(iK_{x\alpha} + 2\pi + \varepsilon_k, \varepsilon_k')^2} \times \frac{|\varepsilon|^{2/\alpha} |\varepsilon'|^{2/\alpha} (k_x' - k_x)^2}{(2\pi/|k_y' - k_y| + |k_y' - k_y| \varepsilon^{-1})^2 + \ldots} \tag{18}
\end{equation}

It can also be advantageous here to rewrite the above integral in terms of the following dimensionless variables: \( x = 4/[\alpha k_x] \), \( x' = 4/[\alpha k_x'] \), \( y = [2/\alpha k_y] \), \( y' = [2/\alpha k_y'] \), \( \varepsilon = \beta \varepsilon \) and \( \varepsilon' = \beta \varepsilon' \). Then, by taking the derivative with respect to \( \omega \), we obtain that \( M_{P_T^x, P_T^x}(T) = C_{2s}^{(3)}(\lambda N) T^{\gamma(2-\gamma)} \) for intermediate temperatures, where the new prefactor \( C_{2s}^{(3)}(\lambda N) \) is again independent of \( T \) and finite in the limit of small \( \epsilon \) and finite \( N \). Moreover, we can follow the same strategy to calculate \( \langle \hat{P}_T^y(\omega) \hat{P}_T^y(-\omega) \rangle_0 \). Indeed, in an analogous way to the previous computation [3], we obtain in the same limit as before that \( M_{P_T^x, P_T^y}(T) = C_{2s}^{(3)}(\lambda N) T^{\gamma(2-\gamma)} \) (with a prefactor \( C_{2s}^{(3)}(\lambda N) \) also independent of \( T \)).

The last step consists of analyzing the off-diagonal terms in the memory matrix, i.e. \( M_{P_T^x, P_T^y} \) and \( M_{P_T^y, P_T^x} \). By performing a similar calculation as outlined above, the leading terms can be shown to vanish in the same limit. Therefore, the memory matrix turns out to be approximately diagonal in the basis \( \{P_T^x, P_T^y\} \) and can be very easily inverted. Indeed

\begin{equation}
M^{-1} \approx \begin{pmatrix}
M_{P_T^x, P_T^x}^{-1} & 0 \\
0 & M_{P_T^y, P_T^y}^{-1}
\end{pmatrix}, \tag{19}
\end{equation}

As a result, by means of Eq. 16, we obtain that the thermal conductivity \( \kappa \) is given by

\begin{equation}
\kappa \approx \frac{1}{T^2} \chi^{2}_{P_T^x, P_T^x}(T) M_{P_T^x, P_T^x}^{-1}(T) + \chi^{2}_{P_T^y, P_T^y}(T) M_{P_T^y, P_T^y}^{-1}(T), \tag{20}
\end{equation}

which yields

\begin{equation}
\kappa \approx A_{xx} T^{\gamma + \frac{3}{2}} + A_{yy} T^{\gamma + \frac{3}{2}}, \tag{21}
\end{equation}

with finite prefactors \( A_{xx} = [C_{2s}^{(1)}(\lambda N)]^2 / C_{2s}^{(4)}(\lambda N) \) and \( A_{yy} = [C_{2s}^{(2)}(\lambda N)]^2 / C_{2s}^{(4)}(\lambda N) \). In the limit of small \( \epsilon \), one can verify that the second term on the rhs in Eq. 21 is subleading. Therefore, assuming the first scenario in which there is no drag effect of the gauge bosons in the system, there will be a regime in which the first term on the rhs of Eq. 21 will dominate over the second term at intermediate temperatures. In other words, we obtain in this work that the thermal conductivity \( \kappa \) of the present model should scale within a certain temperature regime as a power-law \( \kappa \sim T^{\gamma} \) with the exponent \( \gamma = 1/2 + 5\epsilon/4 \), due to non-critical Umklapp scattering of the spinons for a finite number of fermionic species \( N \) and a small parameter \( \epsilon = \eta - 2 \). As a consequence, we can infer from this result that a possible tendency towards a linear behavior as a function of \( T \) in the thermal conductivity of this model with \( \kappa \sim T^{\gamma} \) for \( 1/2 < \gamma \leq 1 \) is indicated qualitatively by our approach at those temperatures. Despite this, we point out that a quantitative comparison with the experimental situation (e.g., in the organic material EtMe₃Sb[Pd(dmunt)₂]₂ [5]) still cannot be rigorously established. This is related to the fact that the IR nontrivial fixed point coupling obtained in this problem for \( \epsilon \rightarrow 1 \) (and finite \( N > 1 \)) becomes strong, which would require the perturbative calculation of the memory matrix and the susceptibilities beyond the lowest-order considered in the present work. Such a more complicated analysis would be valuable in order to carry out a precise comparison of the present theoretical prediction with the experimental situation.

Next, we move on to discuss the second scenario in which there could be the drag effect associated with the gauge bosons and, consequently, those excitations are never in equilibrium in the system. In this case, as was explained before, we must set \( \eta = \eta' \) in Eqs. 9, 10 and 11. The rest of the calculus proceeds essentially in a similar way as was performed for the previous scenario, with only minor modifications. Most importantly, one of the leading terms consisting of \( \langle \hat{P}_T^x(\omega) \hat{P}_T^x(-\omega) \rangle_0 \) discussed previously becomes for the present case

\begin{equation}
\langle \hat{P}_T^x(\omega) \hat{P}_T^x(-\omega) \rangle_0 = \frac{4}{\lambda^2 N^2} \sum_{x,\alpha} g^2 \int_{k, k'} \int_{\varepsilon, \varepsilon'} \frac{f(\varepsilon)f(\varepsilon')}{(iK_{x\alpha} + 2\pi + \varepsilon_k, \varepsilon_k')^2} \times \frac{|\varepsilon|^{2/\alpha} |\varepsilon'|^{2/\alpha} (iK_x)^2}{(2\pi/|k_y' - k_y| + |k_y' - k_y| \varepsilon^{-1})^2 + \ldots}, \tag{22}
\end{equation}

from which follows that the thermal conductivity of the system in this second scenario would be modified to \( \kappa \sim T^{\gamma'} \) with the exponent being \( \gamma' = 5/2 + \epsilon/4 \). Since this latter theoretical prediction is not observed experimentally, this may suggest that the first scenario appears to be more appropriate to describe the transport properties of the candidate spin-liquid phase of the organic material EtMe₃Sb[Pd(dmunt)₂]₂ in the literature [5].
Another important point we want to emphasize here is that, at very low temperatures, Umklapp processes turn out to be exponentially suppressed as a function of temperature and, in this regime, they cannot provide any longer an efficient mechanism to degrade the total momentum of the spinons in the present model. As a result, the thermal conductivity of the system in the clean limit is eventually expected to become exponentially enhanced at very low temperatures. We thus conclude that, in this low-$T$ regime, extrinsic mechanisms for momentum relaxation (such as, coupling to disorder) must be taken into account to produce a finite heat current in the system. If the disorder is extremely weak, Umklapp processes dominate the transport properties of the system for a reasonably wide range of experimentally measured temperatures, as obtained in the present work. Despite this, one can verify from dimensional analysis that coupling the spinons (and also the gauge bosons) to impurities in the present model always represents a relevant perturbation near the IR nontrivial fixed point. Therefore, for very low temperatures, a crossover of $\kappa$ to a different temperature dependence is expected. We leave open this problem here, since it is beyond the scope of the present work. We plan to perform a detailed analysis of the role played by disorder in the present system in a future publication.

Lastly, we point out that the field theory model defined by Eq. (1) has some similarities with the theory associated with quantum criticality near a Pomeranchuk phase transition. Indeed, in Eq. (1), if we alter the condition for the coupling constant in the model from $g_s = s g$ (where $s = \pm$) to $g_s = g$, the resulting theory will describe instead an Ising-nematic transition out of a metallic state which breaks the point-group rotation symmetry of the lattice but preserves translational symmetry [14, 17, 35, 38]. It would be very interesting to apply similar analytically controlled methods to calculate the thermal conductivity of such quantum critical metals in the presence of both Umklapp and disorder to treat the competition between those two effects. There is an ongoing effort in this direction using many techniques by several groups (see, e.g., Refs. [26, 29, 31, 39, 40]). In an important recent work, Ref. [30] provided a thorough analysis of the impurity effects in the calculation of the resistivity for this latter problem using the memory matrix formalism. As a result, they pointed out that it is crucial to treat the effects of random-field disorder on the order parameter in such a system at very low temperatures in a completely nonperturbative way. In this respect, it goes without saying that comparing all the results regarding the transport coefficients of the different models described here in this work with other analytically controlled approaches to those problems based on, e.g., holographic methods would also be extremely helpful.

I would like to thank Sung-Sik Lee and, especially, T. Senthil for very useful discussions. I acknowledge financial support from CNPq under Grant No. 245919/2012-0 for this project.

[34] In fact, one has to be careful in this case because of the gauge boson contribution in Eq. (5). Nevertheless, this term gives a subleading contribution that vanishes in the limit of small $\epsilon$ and finite $N$.
