ABSTRACT: A reactive high-valent dinuclear nickel(IV) oxido bridged complex is reported that can be formed at room temperature by reaction of [(L)2Ni(II)2(μ-X)3]X (X = Cl or Br) with NaOCl in methanol or acetonitrile (where L = 1,4,7-trimethyl-1,4,7-triazacyclononane). The unusual Ni(IV) oxido species is stabilized within a dinuclear tris-μ-oxido-bridged structure as [(L)2Ni(IV)2(μ-O)3]2+. Its structure and its reactivity with organic substrates are demonstrated through a combination of UV−vis absorption, resonance Raman,1H NMR, EPR, and X-ray absorption (near-edge) spectroscopy, ESI mass spectrometry, and DFT methods. The identification of a Ni(IV)-O species opens opportunities to control the reactivity of NaOCl for selective oxidations.

INTRODUCTION

Metalloenzymes are central to the functioning of biological systems, especially in oxidative transformations and protection against reactive oxygen species.1 Fe-, Cu-, and Mn-dependent metalloenzymes have been studied extensively and have stimulated the design and synthesis of structural and functional model complexes, especially in the search for synthetic analogues of reactive bioinorganic intermediates.2 Recently, attention has turned to synthetic nickel-based complexes due to both enzymes such as NOD (nickel oxide dismutase)3 and their potential in the activation of small molecules, including H2O2,4 mCPBA,5 and NaOCl.6 In the latter case, such complexes open the possibility to achieve selective alkane chlorination and alkane and alkene oxygenation.

Recently, several high-valent (Ni(III)4,7 and Ni(IV)6c,8) intermediates were identified spectroscopically. In contrast to organometallic Ni(IV) complexes,8 the formation of Ni(III) and, more so, Ni(IV) oxido complexes, although inferred, is controversial due to the implications of the oxo-wall premise.9 Nevertheless, several Ni(II) and Ni(III) oxido or peroxido complexes, formed with O2 and H2O2, have been characterized already at low temperature.24−27

Here we show that a novel room-temperature-stable dinuclear Ni(IV) oxido complex (3), [(L)2Ni(IV)2(μ-O)3]2+ (where L = 1,4,7-trimethyl-1,4,7-triazacyclononane), can be generated by reaction of the Ni(II) complexes (1, 2) with NaOCl (Scheme 1). The high oxidation state of 3 is stabilized by the tris-μ-oxido-bridged dinuclear structure. Furthermore, the reactivity of 3 toward direct C−H oxidation of organic substrates is demonstrated.

Complex 3 is obtained within seconds of addition of near stoichiometric amounts of NaOCl to [(L)2Ni(II)2(μ-X)3]X·(H2O)n (where X = Cl (1) or Br (2), n = 5 or 7)10 in methanol or acetonitrile at room temperature. The structure of 3 was elucidated through a combination of UV−vis absorption and resonance Raman spectroscopy and ESI mass spectrometry,
supported by isotope labeling, crossover experiments, and DFT methods.

**RESULTS AND DISCUSSION**

Complexes 1 and 2 were prepared by methods analogous to those reported earlier (see SI for details). The Raman spectra of 1 in the solid state (Figure S1) and in solution (i.e., methanol, acetonitrile, Figure S2) indicate that the complexes retain their structure; that is, the ligand (L) remains bound to Ni(II) upon dissolution. However, ESI mass spectrometry indicates that 1 can form mononuclear complexes with three (176.3 m/z: 4 [(L)Ni(II)(CH3CN)3]2+) or two acetonitrile ligands (155.9 m/z: 5, [(L)Ni(II)(CH3-CN)2]) by substitution of the chlorido ligands (Figure S3). Indeed, mixtures of 1 and 2 show rapid exchange of Cl− and Br− ligands (Figure S4). The 1H NMR spectrum of 1 in acetonitrile shows paramagnetically shifted and broadened signals at ca. 60, 90, and 120 ppm (Figure S5), and its UV–vis absorption spectrum in methanol and acetonitrile (Figure S6) shows bands at 384, also an overall intermediate spin state (S = 1) was obtained, consistent with observations by Wieghardt et al.11 The Cu1-symmetric DFT structure for both 1 and 2 is in excellent agreement with the X-ray structure,11 with differences of ca. 0.01–0.02 Å between DFT and X-ray for Ni–N, Ni–Cl/Br, and Ni–Ni distances (Table S1). The antiferromagnetically coupled state lies lowest in energy (including COSMO solvation17 and ZORA18 relativistic effects, Table S2),14,15 in excellent agreement with experiment.11 In this state, the locally spin-polarized triplet (S = 1) Ni(II) ions couple antiferromagnetically (AFM) to reach overall an open-shell singlet state. As a result, spin-up spin-density is observed around one Ni and spin-down around the other (Figure 1). This AFM state is only 0.3 kcal·mol−1 lower than the ferromagnetically (FM) coupled (S = 2) state (see SI section 7 for the corresponding spin-density plot). Both states would be consistent with the paramagnetic 1H NMR shifts (vide supra), but the AFM state is found to be slightly lower by both theory and experiment. The diamagnetic closed-shell singlet state, in which the Ni(II) ions are now locally in a closed-shell (S = 0) state, is higher in energy than the AFM state by 37.7 kcal·mol−1 (1) and 35.0 kcal·mol−1 (2). Finally, also an overall intermediate spin state (S = 1) was obtained, 25.5 kcal·mol−1 (1) and 23.4 kcal·mol−1 (2) higher in energy than the AFM state, where spin-density corresponding to the single occupation of an antibonding dxy orbital was observed on both Ni ions. Finally, the experimental NMR and UV–vis absorption spectra of the AFM state are similar to those of related Ni(II) complexes (Figure S7).16

Addition of NaOCl to 1 or 2 in methanol or in acetonitrile leads to a rapid increase in absorbance at 363 and 612 nm due to formation of 3 (Figure 1). In methanol, the visible absorption band decreases with a t1/2 of ca. 50 s at 20 °C (Figure S8), and the absorption spectrum after 20 min is similar to the initial spectrum, with only a minor shift from 388 to 378 nm (Figure 2). Notably, the rate of decay of 3 in methanol was substantially lower than the rate of the direct reaction of NaOCl with methanol in the absence of 1 (Figure S8), indicating that the formation of 3 competes with oxidation of methanol by NaOCl and that 3 is less reactive in the oxidation of methanol than NaOCl.

In both the presence and absence of 1, near-quantitative (cf. NaOCl) oxidation of methanol to formaldehyde occurs (1.5:1, Figure S9), indicating that although at least 2 equiv of NaOCl are consumed in forming 3 from 1, these oxidation equivalents are still available for subsequent oxidation of methanol. Further additions of NaOCl in the presence of 1 resulted in the reappearance of the 612 nm absorption (Figure S10), confirming the integrity of the catalyst under reaction conditions. Similar changes were observed with NaOBr (Figure S11), which indicates that the same intermediate is formed with both oxidants (vide infra). Addition of H2O2 or purging with O3 (Figures S12 and S13) did not result in the appearance of 3. Intermediate 3 forms upon addition of NaOCl to 1 also in acetonitrile (absorbance band at 612 nm), but persists for a substantially longer time period than in methanol, with a t1/2 of ca. 10 min at 20 °C and over 6 h at −15 °C (Figures S14 and S15), enabling characterization by resonance Raman spectroscopy, XANES, XES, and ESI mass spectrometry and reactivity with other substrates to be studied (vide infra). The maximum transient absorbance at 612 nm was obtained with 3–4 equiv of NaOCl (Figure S16) and is accompanied by an increase in oxidation state as confirmed by XANES and XES (Figure 3 and Figure S17).

The Ni K edge X-ray absorption near edge structure (XANES) as well as the X-ray emission (XES) spectra were recorded for 1 (30 mM) in acetonitrile before and after addition of NaOCl. Spectra were acquired over 5 min after addition when the concentration of 3 (generated from 1) was substantial, although Ni(II) species are present also. The Ni K edge XANES spectra of both 1 and the mixture of species formed after addition of NaOCl show a nondescript edge, i.e.,

---

**Figure 1.** Spin-density plot (S12g/TZ2P) for (antiferromagnetically coupled) 1 with spin-up spin-density shown in blue (around Ni1, left) and spin-down spin-density in red (around Ni2, right).

**Figure 2.** UV–vis absorption spectrum of 1 (3.5 mM) in methanol before (black) and after (red 6 s, blue 48 s, green 463 s) addition of 11 equiv of NaOCl(aq) at 293 K. Inset: Expansion of the NIR region. The data indicate that for 3 f612 nm > 715 M−1·cm−1.

---
The three broad signals in the $^1$H NMR spectrum of 1 in acetonitrile decrease upon addition of NaOCl, suggesting the formation of a diamagnetic species, and then recover concomitant with the increase and decrease in absorbance at 612 nm (Figure S18). Samples flash frozen to 77 K at any time, however, did not indicate the presence of a mononuclear Ni(III) species by X-band EPR spectroscopy.

Generation of 3 by electrochemical oxidation of 1 was explored also. The cyclic voltammetry of 1 shows irreversible redox waves at 1.52, 1.35, and 1.05 V and an irreversible redox wave at 0.58 V on the return cycle. At higher scan rates (up to 10 V s$^{-1}$) the initial oxidation wave at 1.05 V shows some evidence of chemical reversibility; however, the shifts in $I_{p,a}$ (which are corrected for $I_{R,a}$) indicate that the oxidation is electrochemically irreversible also (Figure S19). Addition of NaOCl to 1 results (after 2 min) in a shift in the oxidation wave to 1.16 V, indicative of ligand exchange, e.g., CH$_3$CN replacing Cl$^-$. It should be noted, however, that the redox chemistry of NaOCl, concentration polarization, and the likely complex series of dis- and comproportionation reactions between 1 and 3 preclude the observation of a redox wave assignable to 3. One hour after addition of NaOCl, a further shift is observed, indicating ligand exchange to form a Ni(II) complex similar to 4 (Figure S20). Notably the voltammetry and spectroelectrochemistry were not affected substantially by the addition of water and NaCl (i.e., at concentrations present under reaction conditions).

The spectroelectrochemistry of 1 in acetonitrile shows that oxidation at 1.2 V leads to essentially no change in the UV absorption (Figure S21a). On the second cycle the redox wave is shifted to >1.58 V; again relatively little change in absorbance is observed, and after reduction below 0.86 V only minor shifts in absorbance at ca. 300 nm are observed, consistent with ligand exchange (Figure S21b). Bulk electrolysis of 1 shows an increase in absorption at 344 nm; however, the EPR spectrum (X-band 77 K) of this sample was silent, and hence oxidation leads to ligand exchange to a Ni(II) complex with a more positive redox potential rather than formation of a Ni(III) or Ni(IV) complex.

Attempts to isolate 3 by flash precipitation with KPF$_6$ yielded the mononuclear Ni(II) compound $\left[\left(L\right)\text{Ni}(II)(\text{CH}_3\text{CN})_3\right]$$_{2+}$ (4) instead, reported earlier by Tak et al. as the B(Ph)$_4$ salt, in which the chlorido ligands are replaced by acetonitrile ligands to form a mononuclear complex (see the SI and Scheme 2). Notably, addition of NaOCl to 4 in acetonitrile results in the same visible absorption spectrum as obtained with 1 (Figure S23), indicating that the formation of 3 is not dependent on the initial form of the LNi(II) complex (with Cl$^-$/Br$^-$/CH$_3$CN) and is consistent with the rapid equilibration of these species in solution. Furthermore, addition of NaOCl (4–10 equiv) to a 1:1 mixture of NiCl$_2$ and the ligand (L) in acetonitrile results in the appearance of the bands at $\lambda_{\text{max}}$ 363 and 612 nm (Figure S24), consistent with a maximum 50% conversion to 3. In the absence of ligand (i.e., only NiCl$_2$·6H$_2$O) the band at 612 nm was not observed (Figure S25).

In earlier reports, the presence of acetic acid was necessary for the formation of high-valent nickel complexes with NaOCl. Addition of acetic acid (4.5 equiv) to 3 in acetonitrile (generated by addition of 4.5 equiv of NaOCl to 1 (0.9 mM)) did not affect the absorbance at 612 nm significantly (Figure S26a). In contrast, addition of acetic acid (4.5 equiv)
prior to addition of NaOCl to 1 (0.9 mM) precluded the appearance of the 612 nm band and hence formation of 3 (Figure S26b).19

The ESI mass spectra of 1 in acetonitrile show signals (m/z) assignable to [Ni(II)(L)(CH₃CN)]⁺ (165.9 m/z), [Ni(II)-(L)(CH₃CN)]⁻ (176.3 m/z), [Ni(II)(L)(Cl)]⁺ (264.1 m/z), and [Ni(II)(L)(Cl)]⁻ (565.2 m/z) (Figure S27). The spectrum obtained from a solution containing 3 shows an additional strong signal at 253.3 m/z with an isotope distribution consistent with two Ni centers (Figure S28), regardless of whether it was generated with NaOBr or NaOCl and with 2 in place of 1 (Figures S29–S33). Notably, however, the signal increased by 3 m/z units with Na¹⁸OCl (Figure S31). The m/z signal at 253.3 is therefore consistent with structures such as the peroxy-bridged 3a,20 [(L)₂Ni(III)(μ-O)(μ-O)-O)³⁻, the mono-μ-oxo-bis-terminal-oxo 3b, [(L)-(O)≡Nii-(IV)-O-Ni(IV)=(O)-L]²⁻, and the tri-μ-oxido-bridged 3, [(L)₂Ni(IV)μ-O-O-O]²⁻ (Scheme 3), with the latter structure 3 favored on the basis of Raman spectroscopy (vide infra) and DFT.21

Scheme 3. Structures (3, 3a, 3b) Consistent with ESI Mass Spectral Data and Calculated Driving Forces for Their Formation from 1

All possible spin states were explored by DFT methods for 3, 3a, and 3b. As expected for the d⁶ Ni(IV) ions in 3, the lowest energy⁴ state corresponds to locally closed-shell singlet (S = 0) Ni(IV) ions. For consistency, we explored the possibility of other spin states and found several higher lying spin states, where, for example, the Ni(IV) ions had locally a triplet (S = 1) state that coupled to form overall a quintet (S = 2) state. However, these other spin states are >27 kcal·mol⁻¹ higher in energy (see Table S2) and will not be discussed any further.

For the d⁷ Ni(III) ions in 3a, the lowest energy⁵ state corresponds to a doublet on each of the metals, which can be FM (S = 1) or AFM (open-shell singlet) coupled. The latter open-shell singlet state is lower in (Gibbs free) energy than the triplet by 2.1 kcal·mol⁻¹, and 5.1 kcal·mol⁻¹ lower than the diamagnetic closed-shell singlet state. All other spin states for 3a are >10 kcal·mol⁻¹ higher in (Gibbs free) energy. The lowest energy for the d⁶ Ni(IV) ions in 3b corresponds to an AFM state, where each of the Ni(IV) ions is found locally in a triplet (S = 1) state. The AFM state is lower than the FM state in 3b by 1.2 kcal·mol⁻¹, with the other spin states higher in energy by >10 kcal·mol⁻¹.

The geometrical parameters for compound 3, which although isostructural to [(L)₂Mn(IV)₂(μ-O)]²⁺,²² are found to be somewhat different. The most prominent feature in [(L)₂Mn(IV)₂(μ-O)]²⁻ is a short Mn(IV)–Mn(IV) distance of 2.30 Å, which is absent in 3, where the Ni(IV)–Ni(IV) is instead 2.46 Å; the latter distance is more similar to the bis-μ-oxo variant [L₂Mn(IV)(O)(μ-O)]₂⁻ (2.62 Å).²² Furthermore, the Ni(IV)–N distance of 2.02 Å in 3 is substantially shorter than in [L₂Mn(IV)(μ-O)]²⁻ (2.11 Å). The Ni(IV)–(μ-O) distance in 3 of 1.85 Å is however similar to that in the Mn(IV) analogue (1.82 Å). Overall, the DFT structure for 3 and the X-ray structure for [(L)₂Mn(IV)(μ-O)]²⁺ are similar, which is apparent when superimposed (Figure S34).

Figure 4. Raman spectra (λex, 532 nm) of 1 (3.5 mM) in acetonitrile (a) and with (b) 4.5 equiv of NaOBr, (c) 4.5 equiv of Na¹⁶OCl, and (d) 4.5 equiv of Na¹⁸OCl. *Solute band. #Raman band from quartz.

The Raman spectrum of 3, with excitation resonant with the visible absorption band, shows enhanced Raman scattering at 801, 631, and 521 cm⁻¹ (Figure 3), with only the band at 631 cm⁻¹ (Δ¹⁸O = 32 cm⁻¹) affected by the use of Na¹⁸OCl. The bands are unaffected by use of OBr⁻ in place of OCl⁻. The DFT-calculated Raman spectrum for [(L)₂Ni(IV)(μ-O)(μ-16/18O)]³⁻ (Scheme 3) shows a penta-atomic asymmetric stretching Ni≡(O)₃–Ni mode at 638 cm⁻¹, which shifted to 609 cm⁻¹ upon isotopic labeling (i.e., Δ¹⁸O = 29 cm⁻¹, Figure S35). Mixed labeling (i.e., varying ratios of ¹⁶O and ¹⁸O) experiments show the series of four bands expected for the four isotopologues and correspond well with the DFT-calculated shifts (Figure 5).

The band at 801 cm⁻¹ corresponds to a symmetric Ni–N stretching (calcld by DFT at 782 cm⁻¹, at the same position upon ¹⁸O labeling), while the band at 521 cm⁻¹ involves mainly a combination of Ni–N and Ni–O stretching (calcld by DFT at 517 cm⁻¹ and at 516 cm⁻¹ upon ¹⁸O labeling). All of the
The co-workers (Ni(tmc))2(H2O)36, which shows an O− stretches at 742 cm
−1, and 689 cm
−1 (768 cm
−1). This conclusion is consistent with the assignment of the intermediate as (Figure S36). Antiferromagnetically coupled dinuclear species were found as lowest energy for 1, 2, 3a, and 3b, while a closed-shell spin state was found for 3 (vide supra); a high-spin Ni(II) (S = 1) ground state was found for 4 and 5. The reactions of 1 with NaOCl to form 3, 3a, or 3b (Scheme 3) were calculated to be exergonic by −92.5, −88.1, and −50.3 kcal mol
−1, respectively; hence, 3 is 4.46 kcal mol
−1 more stable than 3a and 42.2 kcal mol
−1 than 3b, in terms of Gibbs energy (in electronic energy: 7.50 and 46.11 kcal mol
−1, respectively for 3a and 3b), Table S3.

Further spectroscopic evidence for the formation of 3, and not 3a or 3b, is obtained by mixed labeling experiments. In these experiments we applied ratios of pure 18O (3:0), pure 16O (0:3), and 1:2/2:1 mixtures of these, such that we would have four different distributions with an average the incorporation of 0, 1, 2, and 3 labeled oxygens into the complex. The observed isotope shifts observed in our Raman spectra with these mixed labeling experiments match perfectly with the corresponding DFT isotope shifts; that is, the 631 cm
−1 peak (630 cm
−1 DFT) shifts to 623 cm
−1 (630 cm
−1 DFT), to 613 cm
−1 (622 cm
−1 DFT), and finally to 599 (609 cm
−1 DFT).

Overall, the spectroscopic and computational data are consistent with the assignment of the intermediate as 3 ([L]Ni(IV)2(μ-18O)3)2+. The mechanism by which 3 forms from Ni(II) complexes undoubtedly involves multiple elementary steps. However, the coordination of OCl− to Ni(II) is expected to be facile given the rapid exchange of Cl−, Br−, and CH3CN ligands. Heterolytic cleavage of Ni(II)−O−Cl to form a transient intermediate Ni(IV) species and Cl− is presumably followed by formation of a (μ-O)2-bridged Ni(IV) dimer, which does not show antiferromagnetic coupling, in contrast with the equivalent manganese complex, but instead corresponds to diamagnetic closed-shell Ni(IV) ions.

Finally, although 3 undergoes rapid self-decay in methanol to yield formaldehyde, in acetonitrile it is relatively stable, allowing for its reactivity with organic substrates to be assessed. The addition of ca. 4 equiv of substrate (e.g., xanthene, 9,10-dihydroanthracene, and fluorene) resulted in a complete loss of absorbance at 612 nm within ca. 6 min (70, 150, and 350 s, respectively, Figure S37). At −15 °C, 3 is stable for over 6 h (Figure S38); however, addition of 4 equiv of xanthene resulted in a rapid loss in absorbance at 612 nm (within ca. 275 s, Figure S39). Addition of 50 equiv of fluorene to 3 resulted in the disappearance of the signal at m/z 253.3 and a recovery of the signals of 1 and 4 (Figure S40). Hence, although substrates react directly with NaOCl, 3 engages in C−H oxidation also (Figure S39).
CONCLUSIONS

Complex 3 represents the first example of a Ni(IV)-oxido-bridged dimer. Its generation from NaOCl and subsequent reaction with organic substrates opens up the possibility to use NaOCl as a terminal oxidant. The intermediary of a transition metal catalyst opens the possibility of engaging in selective oxidations, thereby taming the reactivity of thiopen do antidotal oxidant.

(18) (a) In the absence of Ni(II) or NaOCl is stable in CH2CN.

(19) This complex is reminiscent of the (μ-η2,η2-disulphido) dinickel(II) complexes with 6-methyl-TPA ligands reported by Itoh et al.; see: Inosako, M.; Kunishita, A.; Kubo, M.; Ogrta, T.; Sugimoto, H.; Itoh, S. Dalton Trans. 2009, 43, 9410–9417.

(20) The formation of species such as O=N(IV)--O=N(IV)==O is highly unlikely, as it is calculated to lie 45 to 58 kcal mol⁻¹ (depending on functional used, e.g., BP86-D3 and S12g) higher in energy than even the peroxo species 3a. Furthermore, DFT calculations indicate a high tendency for a species to converge to the structure of the 3a species. In addition ligand hydrolysis can be discounted on the basis of the recovery of the Ni(II) complexes, e.g., 1 and 4 on, once 3 has reacted with solvent or substrate.
