Received: date / Revised version: date

Abstract. The baryon production mechanism at the intermediate $p_T$ (2 - 5 GeV/c) at RHIC is still not well understood. The beam energy scan data in Cu+Cu and Au+Au systems at RHIC may provide us a further insight on the origin of the baryon anomaly and its evolution as a function of $\sqrt{s_{NN}}$. In 2005 RHIC physics program, the PHENIX experiment accumulated the first intensive low beam energy data in Cu+Cu collisions. We present the preliminary results of identified charged hadron spectra in Cu+Cu at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV using the PHENIX detector. The centrality and beam energy dependences of (anti)proton to pion ratios and the nuclear modification factors for charged pions and (anti)protons are presented.

PACS. 25.75.Dw

1 Introduction

One of the most surprising observations at RHIC is a particle type dependence of hadron yield suppression at the intermediate transverse momentum $p_T$ (2 - 5 GeV/c) [1,2]. In Au+Au central collisions at $\sqrt{s_{NN}} = 200$ GeV, yields for mesons are largely suppressed [3] with respect to the yields in proton-proton collisions in the intermediate $p_T$, while those for baryons are not suppressed, and show a binary nucleon-nucleon collision ($N_{coll}$) scaling. In d+Au experiment at RHIC, there is also a particle type dependence in the nuclear modification factor $R_{AA}$ [4]. The $R_{AA}$ for protons in d+Au is larger than that for pions and kaons. This observations can be understood by Cronin effect [5,6]. It is found, however, that the particle species dependence in d+Au is not large enough to account for the absence of suppression for protons as seen in Au+Au central collisions at RHIC. This phenomena in Au+Au central collisions is called "Baryon Anomaly at RHIC". To explain the baryon anomaly, many theoretical models have been proposed, such as quark recombination models [7], and a hybrid model of hydrodynamics with a color glass condensate (CGC) and jet quenching [8]. All of these models are able to reproduce the experimental data qualitatively for both pions and protons.

On the elliptic flow ($v_2$) measurements, there is a also clear particle species dependence [9]. The number of constituent quark scaling of $v_2$ shows a clear universal curve regardless of the particle species, and these scaling properties support the quark recombination picture for the hadron production at RHIC.

In order to test the quark recombination picture, $\phi$ meson is one of the ideal test particles, because the mass is similar to protons', but it's a meson particle. If the hydrodynamical collective flow is a dominant source of baryon anomaly, $\phi$ meson's $R_{AA}$ should follow the data for protons (no suppression) due to its heavy mass. Thanks to the high statistics data in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV taken in 2004 RHIC run, it is confirmed that the $R_{AA}$ for $\phi$ mesons behaves like a meson [10], and its $v_2$ follows the same universal quark number scaling curve of all other particle species [11]. Giving the fact that $\phi$ mesons behave like a "meson", it is now widely believed that the quark recombination is one of the main mechanisms for the hadronization process at the intermediate $p_T$ in central Au+Au collisions at RHIC.

Now the key questions are; where the onset of the baryon anomaly is, and how they evolve as a function of beam energy. In order to answer these questions, the lower energy beam data in Cu+Cu collisions were taken during the 2005 RHIC run by the PHENIX experiment. In this paper, we present the preliminary results of single particle $p_T$ spectra for identified charged particles in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ GeV and 62.4 GeV measured by the PHENIX experiment. The beam energy and centrality dependences of the particle ratios and nuclear modification factors are presented and discussed.

2 PID charged particle spectra analysis

The low beam energy data sets in Cu+Cu have been taken during the 2005 RHIC run. We analyzed 5.2 M minimum bias events for 22.5 GeV Cu+Cu, and 66.5 M minimum bias events for 62.4 GeV Cu+Cu data set. We constructed the tracks within a collision vertex $\pm 30$ cm from the center of the spectrometer.
Charged particle tracks are reconstructed by the Drift Chamber (DC) based on a combinatorial Hough transform. The first layer of Pad Chamber (PC1) is used to measure the position of the hit in the longitudinal direction (along the beam axis). When combined with the location of the collision vertex along the beam axis (from the Beam-Beam Counter (BBC)), the PC1 hit gives the polar angle of the track. Only tracks with valid information from both the DC and PC1 are used in the analysis. In order to associate a track with a hit on the high resolution Time-of-Flight detector (TOF), the track is projected to its expected hit location on the TOF. Tracks are required to have a hit on the TOF within $\pm 2\sigma$ of the expected hit location in both the azimuthal and beam directions. The charged particle identification (PID) is performed by using the combination of three measurements: time-of-flight from the BBC and the TOF, momentum from the DC, and flight path length from the collision vertex point to the hit position on the TOF.

The geometrical acceptance and the in-flight decay are corrected by the GEANT based Monte Carlo simulation. No occupancy correction (detector inefficiency correction due to the high track densities) is applied. The expected occupancy correction is below 4% in Cu+Cu collisions 62.4 GeV at the most central events and less for peripheral collisions, the correction is negligible. No weak decay feeddown correction is applied for proton and antiproton spectra in this analysis.

### 3 Results

We present the following preliminary results in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ GeV and 62.4 GeV, measured by the PHENIX experiment. (1) the identified charged particle $p_T$ spectra, (2) particle ratios ($p/\pi^+$, $\bar{p}/\pi^-$) as a function of $p_T$ for each centrality class, and (3) the nuclear modification factor $R_{AA}$ for pions and (anti)protons as a function of $p_T$.

#### 3.1 $p_T$ Spectra

Fig. 1 and Fig. 2 show the centrality dependences of $p_T$ spectra for protons in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV, respectively. No feeddown correction is applied.

The centrality determination in Cu+Cu collisions 22.5 GeV is purely based on the PC1 hit multiplicity in order to avoid an effect of the spectator nucleons. Since at $\sqrt{s_{NN}} = 22$ GeV the beam rapidity gap is quite narrower than those at the higher beam energy, the BBC (located in $3.0 < |\eta| < 3.9$) is able to see the spectator nucleons. The PC1 multiplicity distribution with the BBC $z$ vertex correction is subdivided into four centrality bins. For Cu+Cu 62.4 GeV data, we use the charge distribution measured by the BBC. We obtain the number of binary collisions ($N_{\text{coll}}$) and the number of participant nucleons ($N_{\text{part}}$) for each data set and each centrality bin by the Glauber Monte Carlo calculation in PHENIX.
GeV and 62.4 GeV, respectively. The \(p_T\) spectra for antiprotons are shown in Fig. 3 and 4. No weak decay feeddown correction is applied for both protons and antiprotons spectra and both beam energies. We measured the spectra in four centrality bins (0-10%, 10-30%, 30-60%, 60-88 or 60-100%) and in the minimum bias events. The \(p_T\) spectra for each centrality bin for \(\pi^{\pm}\) and \(K^{\pm}\) are also measured at both beam energies (see [12]).

### 3.2 Particle ratios (\(p/\pi^+\) and \(\bar{p}/\pi^-\))

Fig. 3 shows the centrality dependence of \(p/\pi^+\) and \(\bar{p}/\pi^-\) ratios as a function of \(p_T\) in Cu+Cu collisions at \(\sqrt{s_{NN}} = 22.5\) GeV. The similar plots for Cu+Cu at 62.4 GeV are shown in Fig. 4.

In 22.5 GeV Cu+Cu data, \(p/\pi^+\) ratio is significantly larger than those in the higher beam energy in Au+Au [11], and it is increasing as a function of collision centrality. This large \(p/\pi^+\) ratios can be understood by the influence of the incoming nucleons from the beams. For \(\bar{p}/\pi^-\) ratios, (almost) no centrality dependence is observed, and the ratios are constant at the value of 0.3 - 0.4 at \(p_T = 2\) GeV/c, which is close to the expected values in the fragmentation and the data in p+p collisions.

In 62.4 GeV Cu+Cu data, the influence of incoming protons is smaller than the one in Cu+Cu collisions at 22.5 GeV, as seen in \(p/\pi^+\) ratios in Fig. 3. The centrality dependence of \(\bar{p}/\pi^-\) is seen. In the most central collisions, \(\bar{p}/\pi^-\) ratio is about 0.6 at \(p_T = 2\) GeV/c, and in the peripheral collisions, the value becomes consistent with that for p+p collisions.

Fig. 4 shows the beam energy dependence of \(p/\pi^+\) and \(\bar{p}/\pi^-\) ratios in Cu+Cu collisions from \(\sqrt{s_{NN}} = 22.5\) GeV to 200 GeV [14]. There is a clear beam energy dependence in Cu+Cu from 22.5 GeV to 200 GeV, i.e. \(p/\pi^+\) (\(\bar{p}/\pi^-\)) decreases (increases) as a function of \(\sqrt{s_{NN}}\), respectively.

For the study of the baryon anomaly at the lower beam energies at RHIC, \(\bar{p}/\pi^-\) ratios would be a good measure, because antiprotons are “produced particles”, but measured protons are the mixture of produced particles and the incoming protons from the beams. The absence of centrality dependence in \(\bar{p}/\pi^-\) ratio in Cu+Cu 22.5 GeV may suggest that there is no baryon anomaly at this beam energy. To conclude this observation, the high statistics data with the heavier collisions system like Au+Au at around 22.5 GeV is necessary in the future RHIC run, and the results should compare with the existing data in Pb+Pb collisions at the SPS energy (\(\sqrt{s_{NN}} = 17.3\) GeV) at high \(p_T\) [13].

### 3.3 Nuclear modification factor: \(R_{AA}\)

To obtain the nuclear modification factors at the lower energy, we used the \(p_T\) spectra at mid-rapidity in p+p collisions at \(\sqrt{s} = 23\) GeV and 63 GeV for kaons and (anti)protons as the reference spectra, measured by the British-Scandinavian Collaboration [15]. Those data are
fitted by the empirical functional form (see [12] in detail). For pions, we use the parameterization as described in [10]. The nuclear modification factor $R_{AA}$ is defined as the following equation:

$$R_{AA}(p_T) = \frac{(1/N_{AA})d^2N_{AA}/dp_Tdy}{(N_{coll})/\sigma_{pp}^{inel} \times d^2\sigma_{pp}/dp_Tdy}, \tag{1}$$

where the $(N_{coll})/\sigma_{pp}^{inel}$ is the average Glauber nuclear overlap function, $T_{A+A}$. The $R_{AA}$ for pions and (anti)protons are shown in Fig. 5 for 22.5 GeV Cu+Cu, and in Fig. 6 for 62.4 GeV Cu+Cu. The centrality selection for $R_{AA}$ is 0-10% central collisions for both beam energies. The values of the average number of collisions used here are $(N_{coll})=140.7$ ($\sigma_{pp}^{inel}=32.2$ mb) for 22.5 GeV Cu+Cu, and $(N_{coll})=152.3$ ($\sigma_{pp}^{inel}=35.6$ mb) for 62.4 GeV Cu+Cu. The systematic error on $R_{AA}$ consists of; (1) $<N_{coll}>$ uncertainty (one $\sigma$ error as shown in dotted-lines above and below $R_{AA}=1$), (2) combined systematic errors from p+p reference data and Cu+Cu spectra (not shown in the figures). The statistical errors are shown in the error bars on each data point.

The data show that there is no suppression on charged pions for both 22.5 and 62.4 GeV Cu+Cu central collisions. For proton’s $R_{AA}$, a clear enhancement is seen and can be attributed to the effect of the incoming beam nucleons. The value of proton’s $R_{AA}$ at 62.4 GeV is slightly smaller than that at 22.5 GeV. $R_{AA}$ for antiprotons is almost unity at the intermediate $p_T$ for both 22.5 and 62.4 GeV, and is very similar to the one for pions.

In 2006, the PHENIX experiment has successfully collected the new reference p+p data at $\sqrt{s_{NN}}=62.4$ GeV. The precision of $R_{AA}$ measurements at 62.4 GeV for both Cu+Cu and Au+Au is expected to be improved by using this new p+p data set.
For Au+Au, increasing as a function of collision centrality.

In summary, we have measured $p_T$ spectra for $\pi^\pm$, $K^\pm$, $p$, $\bar{p}$ in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV.

In 22.5 GeV Cu+Cu data, we observed a larger $p/\pi^+$ ratio compared to those at the higher beam energy in Au+Au, increasing as a function of collision centrality. For $\bar{p}/\pi^-$ ratio, almost no centrality dependence is seen, and the ratio is about 0.3 - 0.4 at $p_T = 2.0$ GeV/$c$, which is close to the value in p+p collisions. In 62.4 GeV Cu+Cu data, $p/\pi^+$ ratios are reduced, compared to those in Cu+Cu 22.5 GeV, and the centrality dependence of $\bar{p}/\pi^-$ is seen. There is a clear beam energy dependence on those ratios in Cu+Cu from 22.5 GeV to 200 GeV, i.e. $p/\pi^+$ ($\bar{p}/\pi^-$) decreases (increases) as a function of $\sqrt{s_{NN}}$, respectively. The observed $\bar{p}/\pi^-$ ratio may suggest there is no baryon anomaly at 22.5 GeV Cu+Cu collisions. To make this point clearer, a further data set (a high statistics low beam energy data in heavy collision system) is necessary in the future RHIC run.

For the $R_{AA}$, no suppression is observed for charged pions for both 22.5 and 62.4 GeV in Cu+Cu central collisions. For protons $R_{AA}$, there is a clear enhancement, which can be attributed to the incoming beam nucleons. The $R_{AA}$ in 62.4 GeV is slightly smaller than that in 22 GeV. The antiprotons $R_{AA}$ is almost unity at the intermediate $p_T$ region for both beam energies.

4 Conclusions

In summary, we have measured $p_T$ spectra for $\pi^\pm$, $K^\pm$, $p$, $\bar{p}$ in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV.

In summary, we have measured $p_T$ spectra for $\pi^\pm$, $K^\pm$, $p$, $\bar{p}$ in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV.

In summary, we have measured $p_T$ spectra for $\pi^\pm$, $K^\pm$, $p$, $\bar{p}$ in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV.

In summary, we have measured $p_T$ spectra for $\pi^\pm$, $K^\pm$, $p$, $\bar{p}$ in Cu+Cu collisions at $\sqrt{s_{NN}} = 22.5$ and 62.4 GeV.
