Successful management of refractory gastric variceal bleeding via a combined percutaneous approach in sinistral portal hypertension

Abstract
Amongst less common upper gastrointestinal bleeding causes is gastric variceal bleeding due to sinistral portal hypertension. A patient with a history of acute myeloid leukemia and subsequent splenic vein thrombosis presented with melena due to gastric varices bleeding. After failure of medical and endoscopic approach and given that he was not a TIPS candidate, a percutaneous approach was attempted. A transhepatic catheterization and ectopic varices embolization initially stabilized him, but bleeding relapsed. A splenic artery embolization was performed that led to permanent management of the bleeding.

Keywords: sinistral portal hypertension, percutaneous transhepatic variceal embolization, splenic artery embolization

Abbreviations: SPH, sinistral portal hypertension; SVT, splenic vein thrombosis; TIPS, transjugular intrahepatic portosystemic shunt; B-RTO, balloon-occluded retrograde transvenous obliteration technique; PTVE, percutaneous transhepatic variceal embolization; MRA, magnetic resonance angiography; EUS, endoscopic ultrasound

Introduction
Gastric varices are present in 20% of patients with cirrhosis, either in isolation or in combination with esophageal varices.1 Although they bleed less frequently than oesophageal varices, the outcome is worse, with high morbidity and mortality.2

Sinistral portal hypertension (SPH) is a rare clinical syndrome that leads to gastric varices formation due to splenic vein thrombosis (SVT) in absence of liver function abnormalities or liver cirrhosis. The most common aetiology of SPH is pancreatic disease including cancer, pancreatitis, abscess formation, or a pseudocyst,3–6 followed by metastatic carcinoma, retroperitoneal fibrosis, Thrombophilia,7–10 pancreatic or splenic lymphoma11 and splenic artery malformations12 or iatrogenic injury. Gastrointestinal bleeding due to ruptured gastric varices is the most common manifestation of this syndrome which can be life-threatening.13–16

Various different treatment approaches have been proposed for gastric variceal bleeding secondary to splenic vein thrombosis. The endoscopic management is the same as in portal hypertension due to cirrhosis. Cyanoacrylate injection achieves haemostasis in more than 90% of the cases (more than one session may be needed) accompanied by secondary prophylaxis with beta blockers.17 However, this approach can either be unsuccessful or not feasible due to inexperienced endoscopist.

Splenectomy is selected for the management of life-threatening, unresponsive to conservative measures variceal bleeding and is performed more often as first choice in SPH in complicated cases of pancreatic disease.4,13 Endovascular procedures such as splenic artery embolization14,19 and trans-hepatic splenic vein stent placement10 have been proved effective, less invasive therapeutic choices in patients unfit for surgical interventions. Another minimally invasive nonsurgical method that directly decompresses portal pressure is transjugular intrahepatic portosystemic shunt (TIPS), although reserved for generalized portal hypertension in cirrhosis. Nevertheless, additional therapy as variceal embolization at the time of the TIPS, may be necessary.20 However, not every patient is candidate for TIPS, as multiple medical conditions could be contraindications to it. Embolization of gastric varices has also been achieved using the balloon-occluded retrograde transvenous obliteration technique (B-RTO) via gastrorenal or gastrocaval shunts. Periodic surveillance of these patients is vital since a small increase in portal pressure may cause rebleeding.21

Myeloproliferative neoplasms are frequently related to non-cirrhotic thrombosis of the splenportal axis.22 Moreover, patients with myelofibrosis and myeloid metaplasia can present with portal hypertension.23 We report a patient with a history of myelofibrosis and recurrent thrombotic episodes, presenting with massive gastric variceal bleeding caused by SPH. We describe the diagnostic and therapeutic approach to this patient and review of the literature.

Case presentation
A 70-year-old man was admitted to the emergency department due to repeated episodes of melena over the last 10 days and progressive fatigue. The patient had a history of thrombophilia (deep vein thrombosis, pulmonary embolism with filter in inferior vena cava), myelofibrosis progressed into acute myeloid leukemia, severe aortic
stenoosis and heart failure, diabetes mellitus and mild renal failure. He had no bleeding episodes in the past. He was already anticoagulated with tosilomucarol (INR:1.61) and on antiplatelet therapy with acetylsalicylic acid.

On admission the patient was pale, with low blood pressure BP:85/50mmHg, tachycardia HR:95/min and his laboratory tests revealed severe anemia Ht:17.8%, Hb:5.2g/dl, MCV:77.7fl, RDW:24%, renal failure (Urea:188mg/dl, Creatinine:1.6mg/dl), hyperkalemia (K:5.6mEq/l, normal range:3.5-5) with normal liver function tests and INR:1.4. After hemodynamic stabilization and transfusion of 6 units of red blood cells and 2 units of fresh frozen plasma, an emergency endoscopy was performed. Large bleeding fundal varices (GOV-2 & isolated) were revealed. Histoacryl was not available at that time and injection sclerotherapy with ethanolamine was attempted. Large thrombus was formed but varices went on oozing. He was commenced on i.v. antibiotics and somatostatin. Splenic vein occlusion/thrombosis was accordingly suspected. An abdominal ultrasound showed enlarged spleen 17cm, with normal liver parenchyma (without any signs of liver cirrhosis), patent portal vein but there was no flow in the splenic vein.

Due to failure of the medical and endoscopic treatment to control bleeding, the patient was again tachycardic with hypotenison (HR:98/ min, BP:90/55mmHg), a percutaneous transhepatic approach was decided as he was unsuitable for TIPS due to cardiac co-morbidities. During selective venography, the splenic vein was found totally occluded and multiple ectopic fundal varices (collaterals) were identified. An emergency percutaneous transhepatic variceal embolization (PTVE) of the patient’s ectopic veins with coils was performed without serious side effects. One week after the ectopic varices embolization the patient had a repeated episode of hematemesis with hemodynamic destabilization (BP:80/45mmHg, HR:105/min). A Sengstaken-Blakemore tube was inserted and a repeat endoscopy revealed multiple fundic varices with cherry red spots, an ulcer on a varix surface and blood clots in the stomach. Blood transfusion with 4 units of red blood cells was given.

At this point we proceeded to an emergency selective embolization of splenic artery with embospheres (more that 70% of the total splenic volume was embolized) (Figure 1A) (Figure 1B). The procedure was well tolerated and proved successful; there was no recurrence of bleeding post-embolization. Mild analgesics were given for left upper abdominal pain and antibiotic administration was continued. Due to peripheral oedema, ascites, pleuritic and pericardial effusion the patient was commenced on diuretic therapy and nutritional support.

He was discharged 2 weeks post splenic artery embolization, clinically improved. Repeat MRI scan of the abdomen 2 months later, revealed liquefaction of splenic parenchyma with high solid content and peripheral enhancement after intravenous injection of contrast medium. These imaging findings were indicative of possible inflammatory content in the liquefied part of the spleen. Six months later spleen was still liquefied, with a substantial reduction in size from 17cm down to 11cm on MRI. No further bleeding episodes were noted after one year of follow up although the patient was repeatedly hospitalized due to complications of cardiac and haematological co-morbidities.

**Discussion**

Non-cirrhotic gastric variceal bleeding results from significant increase in pressure of the left-sided portal circulation. It is important, but not always easy, to differentiate between sinistral and classical portal hypertension since the optimal management is quite different. Thrombotic occlusion of the splenic vein is the primary cause of SPH with pancreatic diseases being the main source of such thrombosis. Myeloproliferative neoplasms account for the majority of non-cirrhotic and non-malignant splanchnic vein thrombosis.

![Figure 1A](image1.png) Selective arteriography of the spleen showing normal arterial vascular tree on an enlarged spleen. The coils from the previous emergency percutaneous transhepatic variceal embolization of the patient's ectopic veins are observed.

![Figure 1B](image2.png) Following embolization with embosphere particles through a microcatheter, angiographic abolishment of peripheral splenic arterial branches is observed.

Diagnostic imaging plays an important role in confirming splenic vein occlusion, but in cases of severe upper gastrointestinal bleeding, hemostasis is the primary goal. Trans-abdominal ultrasonography and doppler ultrasonography of the splenopetal axis is usually used to differentiate between systemic versus sinistral portal hypertension. When transabdominal ultrasound is non-diagnostic, other modalities such as endoscopic ultrasound (EUS), CT scan, magnetic resonance angiography (MRA) could have better accuracy. Undertoubtedly, the gold standard in diagnosing sinistral portal hypertension is angiography.

Fundic variceal bleeding can be life-threatening and direct intervention is more than crucial. Endoscopic approaches or TIPS used as treatment for refractory haemorrhage from varices in cirrhotic patients, show marginal benefit in sinistral hypertension. Therapeutic choices for bleeding control include injection therapy (tissue adhesives) and less often band ligation as first-line endoscopic therapies. More sophisticated interventional radiologic techniques and splenectomy are selected especially in cases unresponsive to conservative management. However, the long-term reblooding rate after endoscopic cyanoacrylate injection is still high in addition to potential risk of systemic migration through the inferior vena cava.

Successful management of refractory gastric variceal bleeding via a combined percutaneous approach in sinistral portal hypertension

Bhat et al. have reported successful, EUS-guided, treatment of gastric fundic varices with combined injection of coils and cyanoacrylate in 152 patients, with a low re-bleeding rate of 3% during long-term follow-up.

PTVE using coils and/or sclerosing agents has been an alternative therapeutic option, significantly lowering variceal rebleeding rate due to a wider obliteration range of collaterals in the vicinity of the gastric fundus. This technique has been widely used either alone or in combination with TIPS or B-RTO in cases of refractory variceal bleeding in cirrhotic patients. PTVE does not always lead to complete eradication of gastric varices, probably due to the presence of multiple inflow vessels and has limitations in cases of ascites. Furthermore, the underlying portal hypertension remains unaffected and recurrent bleeding has been reported in several cases within a few months after embolization. For this reason, PTVE is considered as an adjuvant rather than radical treatment. B-RTO is an invasive endovascular technique for gastric varices obliteration, using a sclerosing agent injected through a balloon catheter. Simultaneous obliteration of the gastrorenal shunt is necessary for preventing bleeding recurrence.

In refractory cases, splenic artery embolization by selective catheterization is an option for patients who are not medically fit for a splenectomy. Wang et al. described 14 cases with sinistral portal hypertension due to pancreatic diseases, and treated with splenic artery embolization, mostly for bleeding complications. The approach was feasible and effective both clinically and radiologically. Similar approach is proposed in a previous report for patients with poor performance status and sinistral portal hypertensive bleeding.

Data are lacking on the role of endovascular portal vein stenting for the management of sinistral portal hypertension. On the contrary, splenectomy has been proved to be an effective alternative treatment option for SPH due to splenic vein thrombosis, minimizing variceal rebleeding rates, although surgery has many limitations in patients with multiple co-morbidities.

In our case a combination of selective transhepatic variceal embolization with coils followed by splenic artery embolization with embospheres, was performed in order to control recurrent gastric variceal bleeding in a high-risk patient with splenic artery thrombosis and multiple co-morbidities. The approach was effective in the long term with minimal side effects and can be considered in similar cases.
