Received October 23, 2017; revised October 23, 2017; accepted December 22, 2017.

A dehiscence of the petrous segment of the internal carotid artery (ICA) is an anatomic variation in which the bony covering of the ICA is partially absent. It has a prevalence in temporal bones of 7.7%¹ and can be associated with pulsatile tinnitus,² which, in our experience, is a complaint with increasing incidence in the daily practice.

Case Report

A 59-year-old female patient with no relevant antecedents, except for cervical complaints, presented with an intermittent right-sided loud low-frequency tinnitus that had been present about 1 month. A pulsatile component, synchronous with her pulse, progressively became apparent during the morning and could also be influenced by cervical movements. Otomicroscopy revealed no abnormalities on either side. Cervical examination showed a bilaterally limited range of motion and pain at the level of the facet joints of C4 to C5. Ophthalmological, vestibular, and neurological clinical examinations were performed, but with little or no effect on the pulsatile tinnitus.

Follow-up audiometry 5 weeks later showed a discrete improvement on high frequencies but no improvement of the pulsatile tinnitus whatsoever. When performing the stapedius reflex decay test without administering stimulation, a pulsatile movement of the baseline (about 72 bpm) could be observed. Magnetic resonance imaging (MRI) of the posterior cranial fossa and magnetic resonance angiography (MRA) of the circle of Willis could not demonstrate an obvious neurovascular conflict. No other vascular malformations, arteriovenous malformations, sinus thromboses, stenoses, signs of benign intracranial hypertension, or other abnormalities were seen on MRI. Consequently, a CT scan of the temporal bones was performed. This examination revealed a large dehiscence of the petrous segment of the ICA anteriorly to the cochlea, just at the level of the medial wall of the eustachian tube (ET) on the right side (Figure 1). Other possible causes of pulsatile tinnitus visible on CT, such as a dehiscence of the superior semicircular canal,³ an ICA-cochlear dehiscence,⁴ and a dehiscence of the ICA in the middle ear,² were excluded.

The patient was subsequently reassured regarding the benign character of this anatomical anomaly, but she was

also informed of the surgical inaccessibility of the established cause of her inconveniences.

**Discussion**

This is, to our knowledge, the first case report in the literature that describes a dehiscence of the ICA at the level of the ET as the cause of pulsatile tinnitus. An earlier histologic temporal bone study showed that in normal temporal bones without cholesteatoma or chronic otitis media, most ICA dehiscences occur at the level of the middle ear (57.14%) and less often at the level of the ET (42.85%).5 Other ICA dehiscences, such as an ICA-cochlear dehiscence4 or a dehiscence of the ICA in the middle ear associated with pulsatile tinnitus,2 have been reported and should be taken in account in the differential diagnosis.

Concerning the diagnostic workup of pulsatile tinnitus, every otologist should keep in mind the possibility of a dehiscence of the ICA, which is difficult to visualize on MRI, usually performed as the first-step modality of imaging in patients with pulsatile tinnitus, and therefore should proceed to a CT scan of the temporal bone. The most important limitation of MRI in the diagnostics of pulsatile tinnitus is the fact that it does not show any bony dehiscences at the level of the middle or inner ear that can cause pulsatile tinnitus.

In the management of a symptomatic dehiscence of the ICA, a conservative attitude is generally adopted. Since the anatomical position of the dehiscence in our case was located at the level of the medial wall of the ET and thus was impossible to surgically approach without sacrificing hearing and/or ET function, the patient was informed of all these facts. She has been doing very well since and is coping with the pulsatile tinnitus in an exemplary fashion.
