Niche switching and leapfrog foraging: movement ecology of sympatric petrels during the early breeding season

Petra Quillfeldt, Henri Weimerskirch, Karine Delord and Yves Cherel

Abstract

Background: The timing of events in the early part of the breeding season is crucially important for successful reproduction. Long-lived animals that migrate large distances independently of each other meet at the breeding sites to re-establish their pair bonds and coordinate their breeding duties with their partners.

Methods: Using miniature light-geolocation and immersion data together with blood stable isotopes, we studied the early breeding season in Thin-billed prions Pachyptila belcheri, Antarctic prions P. desolata and Blue petrels Halobaena caerulea breeding at Kerguelen Islands in the Indian Ocean. These three species exhibit differences in their winter habitat and timing of migration, moult and breeding. We hypothesised that these differences would influence their behaviour during the early breeding season.

Results: In line with our hypothesis, we found clear differences not only in the timing of colony attendance, but also in the time budgets while at sea and in habitat use. Both early breeding Blue petrels and late breeding Antarctic prions spent about 8 h per day in flight and 15 h foraging. In comparison, Thin-billed prions, which breed in mid-summer, spent less time (5 h daily) in flight and more time (18 h daily) foraging, thus maximizing the time spent foraging during the longest daylight days of the year. While the ecological habitat parameters (sea temperature, wind, productivity) of Thin-billed prions and Blue petrels were relatively stable throughout the year, Antarctic prions showed clear niche switching, caused by leapfrogging between the northernmost winter distribution to the southernmost distribution during the early breeding season. Blood stable isotopes confirmed the habitat switch between the inter-breeding and early breeding periods and highlighted trophic segregation with Blue petrels feeding more on fish and Antarctic petrels more on crustaceans during the early breeding period.

Conclusion: We found that the three sympatric petrel species segregated in time and space, both in the winter and the early breeding season. The interplay of timing and distribution meant that the three species show the full range of migratory strategies, from niche-tracking Blue petrels to niche-switching Antarctic prions. The latitudinal distribution resembled the leapfrogging of terrestrial avian migrant species or populations.

Introduction

Animals often aggregate in large numbers at rich foraging grounds and suitable breeding sites. This aggregation may lead to intense competition for resources [1] and reduced foraging efficiency [2]. Interspecific competition can be reduced by ecological segregation [3] and according to the niche theory, segregation in some dimension of the n-dimensional niche hyper-volume between sympatric species is essential for their coexistence in sympathy (e.g., [4–6]). Niche differentiation thus separates sympatric species and promotes coexistence of ecologically similar species via their segregation.

Possible dimensions of segregation include habitat, resource, and temporal axes [7]. Habitat segregation can be seen as differences in foraging areas [8, 9] or diving depths [9, 10], and species differences in prey choice (e.g. [11, 12]) arise from resource segregation. Differences at temporal axes such as in the timing of breeding may also be important, because they determine the time of the highest energy demand in each species in relation to the accessibility of prey. In addition to the timing of events within the year, the daily timing of foraging may also be crucial, for example if nocturnal seabirds take advantage of the daily vertical migration of marine organisms.

A good example for aggregated animals can be found in seabirds that often aggregate in large numbers at suitable breeding colonies on oceanic islands and at other protected sites. In a previous study, we investigated spatial segregation in the winter distribution of closely related petrel species breeding sympatrically in the southern Indian Ocean [13], as these highly mobile petrels offer fine models of evolution of diversity along environmental gradients. The Blue petrel (Halobaena caerulea, BP) is the only member of the genus Halobaena, and the sister group to the prions (e.g. [14]). We found that Thin-billed prions (Pachyptila belcheri, TBP), Antarctic prions (Pachyptila desolata, AP) and blue petrels from the Kerguelen archipelago in the southern Indian Ocean segregated latitudinally: Antarctic prions spent the winter north of the Polar Front in temperate waters, whereas Thin-billed prions preferred intermediate latitudes and temperatures and blue petrels were found south of the Polar Front in Antarctic waters. This near complete niche separation across a large-scale ecological gradient without physical barriers was also reflected in stable isotope values of feathers, suggesting evolutionary isolation by environment.

The aim of the present study was to investigate ecological segregation of Antarctic prions, Thin-billed prions and Blue petrels during the early part of the breeding season, from the arrival at the colony to the first incubation shift. In addition to winter habitat choice, these species differ in their timing of migration and molt of flight feathers [15]. While Blue petrels and Thin-billed prions molt during the post-breeding period in polar waters, Antarctic prions molt several months later, in the pre-breeding period, and further north, in warm subtropical waters [15].

We hypothesised that these differences, and the different environmental conditions experienced during the winter, would influence their behaviour during the early breeding season. In the present study, we used biologging data to: (i) compare colony attendance patterns among the three species, (ii) determine the foraging areas used during the pre-laying exodus and early incubation, and (iii) examine the activity data of tracked birds during the early breeding season. We also investigated the isotopic niche of the equipped birds during the early breeding season by measuring blood δ13C and δ15N values as proxies of their foraging habitat and diet/trophic position, respectively [16].

Materials and methods

Fieldwork, study species and data loggers

Fieldwork was carried out at the subantarctic Kerguelen archipelago in 2011–2013. To investigate the timing and spatial extent of movements, we attached leg-mounted miniaturized saltwater immersion geolocators (MK10, developed by British Antarctic Survey, Cambridge, UK) to breeding adults at two adjacent islands in the Golfe du Morbihan, Ile Mayes (49°28′S, 69°57′E) and Ile Verte (49°31′S, 70°04′E), where large numbers of BP and TBP, and of AP breed, respectively (for sample sizes, see Table 1). Nests were selected according to accessibility, and the birds were captured by hand at the nests during incubation. The geolocators weighed 1 g (< 1% of the mean body mass) and were fixed to plastic leg bands. Tagged individuals were marked with numbered steel rings on the other leg. A blood sample (0.1 ml) for sex determination was taken from the brachial vein and stored on FTA cards. Burrows were revisited and devices retrieved during early incubation in the following season (Table 1), and birds were blood sampled for stable isotope measurements (0.2–0.4 ml from the brachial vein). All birds were equipped with geolocators during the 2011/2012 breeding season and the data in this study correspond to the beginning of the 2012/2013 breeding season. Because several loggers stopped recording several months before device recovery, the final sample sizes for year-round tracks, which were used in this study, were smaller than for recovered data sets. A detailed study found no evidence for any substantial impact of the geolocators on Thin-billed prions: breeding performance was unaffected in the season of attachment or following recovery; eco-physiological measurements suggested that adults adapted to the higher load; and the similarity in stable isotope ratios in blood and feathers of...
instrumented adults and controls indicated that general diet and distribution was unaffected [17].

The breeding chronology and colony attendance vary among the species. The following features are notable: (i) fledging occurs in February in both BP and TBP, and later, in April, in AP; (ii) unlike prions, adult BP transiently return to their burrows in fall during a post-breeding visit [18, 19]; (iii) BP return to the colony in early September, while TBP and AP arrive later, in October and November, respectively; (iv) importantly, AP lays later than the two other species, with laying occurring on average 40 days later than in its closely-relative TBP [20].

The transition from the non-breeding to the breeding season starts with the re-occupation of the nest site, pair-bond re-establishment and mating. During this phase, Procellariiformes typically spend a high proportion of their time ashore, where they fast and lose weight [21]. To recover body condition and in the case of the females, to feed up for egg production, both male and female petrels often fly long distances to areas of high resource abundance during an extended foraging trip before laying - the pre-laying exodus or 'honeymoon period' [22]. As soon as the female returns from the pre-laying exodus, she lays a single egg, and departs again, while the male usually takes the first long incubation shift [21].

Sex determination
The sex of each bird in this study was determined through PCR using primers 2550 and 2718 that amplify sections of the sex-linked chromo-helicase-DNA binding (CHD) gene [23]. DNA was extracted from 50 μl blood using a Qiagen DNAEasy blood purification kit (Qiagen, Hilden, Germany). Each reaction was carried out in 25 μl, containing 10 ng template DNA, 1 × PCR buffer, 0.1 mM DNTPs, 2.5 mM MgCl2, 0.2 μM of each primer and 0.1 U Taq polymerase (Firepol, Soilih Biodyne, Tartu). Thermocycling consisted of an initial denaturation step of 2 min at 94 °C, followed by 35 cycles denaturation at 94 °C for 30 s, annealing at 54 °C for 30 s, extension at 72 °C for 1 min, and ended with two expansion steps of 42 °C for 1 min and 72 °C for 10 min. PCR products were visualised on a 2% agarose gel, with a single band at ~650 bp indicating a male, and two bands at ~450 and ~650 bp indicating a female.

Data processing
Geolocators provide two positions per day based on light levels, with an accuracy of approximately 186 ± 114 km [24]. Light data were analysed using the BASTrak software suite (British Antarctic Survey, Cambridge, UK). TransEdit was used to check for integrity of light curves and to determine dawn and dusk times, and Locator to estimate the latitude from day length and longitude from the time of local mid-day relative to Greenwich Mean Time. We assumed a sun elevation angle of −3.5°, based on known positions obtained during pre- and post-deployment calibration of the loggers at the colony. All estimated locations were examined visually in a geographical information system (GIS) and any unrealistic positions – either associated with interference to light curves at dawn or dusk, or in proximity to equinoxes when latitudes are unreliable - were excluded from further analyses. We systematically excluded latitude position estimates during 1 week before and after the equinox, and any positions that were unrealistic during 2 weeks before and after the equinox.

Trips to sea were distinguished from periods in the burrow by examining the light and immersion data. Following [25], the occurrence of complete daytime darkness in the logger trace allowed identification of days spent in the colony, whilst sustained periods of night-time dryness in the immersion data allowed identification of visits to the burrows during the night. This allowed determining the day (or night) of first arrival in the colony arrival to the colony, which was followed by the “pre-exodus phase”, i.e. the period from first arrival to the start of the pre-laying exodus. During this phase, we determined the total number and proportion of days spent in the burrow. In addition to determining only days at the colony and days at sea (e.g. [26]), we here distinguished another category, namely days at sea followed by nights in the burrow. The pre-laying exodus was an obvious phase lasting 14–52 days when the bird was at sea, which preceded the first incubation shift. Days away from the nest during the incubation shifts indicated egg neglect (also termed intermittent incubation), a common strategy in petrels and some other offshore feeders (e.g. [27]).
The activity (i.e. saltwater contact) analyses were carried out with the online tool Actave.net [28] were used to describe the birds’ behaviour at sea. The devices recorded saltwater immersion every 3 s as proxy for activity patterns and store the sum of positive tests once every 10 min. Hence, each recorded time-stamped immersion value (denoted \( \varepsilon \)) can range from 0 (no immersion) to 200 (permanent immersion). Actave.net’s standard setting define immersion as follows (i) time in flight: the sum of all 10-min intervals with \( \varepsilon = 0 \) (dry), (ii) time (sitting) on water: the sum of 10-min intervals with \( \varepsilon = 200 \) (wet), and (iii) foraging time: the sum of 10-min intervals with \( 0 < \varepsilon < 200 \) (intermediate). Hence, the bird’s behaviour was defined using the less arbitrary and most conservative threshold \( \varepsilon \) values, namely 0 and 200. BP and prions use different feeding techniques, including surface-seizing, surface-filtering, shallow-plunging, hydroplaning and dipping [18]. These methods involve actively transitioning from air to water; accordingly, foraging time was here identified as intermittent wet and dry states for at least one 10 min period. Although such records probably include non-foraging behaviours (e.g. preening, stretching), we believe that they represent a reasonable indicator of foraging activity of the birds [29].

The following habitat parameters were obtained through the Environmental Data Automated Track Annotation System (Env-DATA) on Movebank (movebank.org): Daytime sea surface temperature (SST) and Chlorophyll a mass concentration near the surface of the ocean (Chla) from MODIS Ocean Aqua OceanColor (4 km, 8 day mean), and the U and V wind components from ECMWF Interim Full Daily SFC Wind (10 m above ground). Wind speed was calculated from the square root of the sum of squares of the V (south to north) and U (west to east) wind components. We have previously shown that coarse-resolution location data are suitable for species distribution modelling despite an offset in the scale with the environmental data [30].

Statistical analyses were conducted using R 3.6.0 [31]. We tested for normality using Kolmogorov-Smirnov tests and by checking plots of the data. Throughout this study all means are given \( \pm \) S.D. To compare habitat parameters a principal component analysis (PCA) of the five environmental parameters (SST, Chla, windU, windV, windspeed) was performed. Factor analysis produces a reduced suite of independent dimensions for modelling, and thus helps to avoid overfitting [32]. The PCA extracted two significant components. PC1 (eigenvalue 1.70) was determined mainly by the U (west to east) wind component \( (R = -0.86) \) and wind speed \( (R = -0.88) \), and thus, was lower in stronger westerly winds. PC2 (eigenvalue 1.14) was determined mainly by Chla \( (R = -0.76) \) and SST \( (R = 0.60) \) and thus, was lower in colder, more productive waters and higher in warmer, less productive waters. Habitat niches plots were created from the two dimensions of the habitat (PC1 and PC2) using kernel densities calculated in R 3.6.0 [31]. (Function kde2d in the R-package MASS).

**Stable isotope analyses**

Carbon and nitrogen isotopic studies from the Southern Ocean show \( \delta^{13}C \) values of seabirds correspond to the location of their latitudinal foraging habitats [33, 34] and their \( \delta^{15}N \) values increase with trophic level [35]. Following [33], the \( \delta^{13}C \) estimations of the Subtropical and Polar fronts for blood were \( -19.7 \) and \( -22.5 \% \), respectively. From North to South they delineate the Subtropical \( (\delta^{13}C \geq 19.7 \%) \), Subantarctic \( (22.5 < \delta^{13}C < -19.7 \%) \) and Antarctic \( (\delta^{13}C \leq 22.5 \%) \) zones.

Whole blood collected during the retrieval of the geolocators was freeze-dried and one sub-sample in the order of 0.3–0.4 mg was weighed with a microbalance and packed in tin capsules. Carbon and nitrogen isotope ratios were measured simultaneously by continuous-flow isotope ratio mass spectrometry (Thermo Scientific Delta V Advantage) coupled to an elemental analyser (Thermo Scientific Flash EA1112). Replicate measurements of internal laboratory standards indicated measurement errors < 0.10 ‰ for \( \delta^{13}C \) and \( \delta^{15}N \). All stable isotope ratios are expressed in \( \delta \) notation as parts per thousand (‰) deviation from the international standards Vienna-Pee Dee Belemnite (carbon) and AIR (nitrogen).

Whole blood \( \delta^{13}C \) and \( \delta^{15}N \) values are very close to those of blood cells because blood cells contain more organic matter than plasma [36]. Bird blood has a turnover time of ca. 4 weeks [37]. Thus, samples taken after recapture of the birds carrying GLS were representative of the early breeding season, in particular the pre-laying exodus. To complete the picture, blood \( \delta^{13}C \) and \( \delta^{15}N \) values were compared to those of body feathers that are indicative of the foraging ecology of the birds during the inter-breeding period [15]. Before comparison, feather values were corrected to take into account tissue-specific isotopic differences [38].

**Results**

**Return to breeding colony**

Arrival times back to Kerguelen (Fig. 1, Fig. S1, Table 2) varied among the species, with Blue petrels arriving in September, Thin-billed prions in October and Antarctic prions in November to early December (Table 3). Arrival dates also differed between sexes (Tables 2 and 3, Fig. 1, Fig. S1), as males arrived earlier, on average.

The pre-exodus phase (i.e. from first arrival at the colony to departure for the pre-laying exodus) lasted 3–27 days, with significant differences between the species and sexes (Tables 2 and 3, Fig. 1, Fig. S1). During the pre-exodus phase, birds spent shifts of 1–19 days in the
burrow (Fig. 1, Fig. S1). In Thin-billed prions, which had the longest pre-exodus phase, burrow visits were alternated with foraging trips lasting 1–13 days (Fig. S1).

Pre-laying exodus
Departure on exodus was in the same order as arrival, i.e. Blue petrels started in September, Thin-billed prions in October and Antarctic prions in November to early December (Fig. 1, Fig. S1, Table 3). We observed no consistent sex differences: Females departed slightly earlier than males in Blue petrels and Thin-billed prions, but the opposite was found in Antarctic prions (Table 3). Likewise, sex differences in the pre-laying exodus duration were species-specific (Tables 2 and 3): Females engaged in longer pre-laying exoduses than males in Thin-billed prions, while the opposite was observed in Blue petrels and Antarctic prions. Females also reached further distances to the colony (Table 4).

The distribution during the pre-laying exodus also differed among the species (Fig. 2). Blue petrels spread most widely longitudinally, and used more northerly latitudes during the exodus than both Thin-billed and Antarctic prions (Table 4, Fig. 2). Thin-billed prions from Kerguelen mainly used open-ocean waters west of the archipelago, and Antarctic prions moved in an easterly direction (Table 4, Fig. 2), and travelled the shortest distance from the colony (Table 4).

![Fig. 1](#) Early breeding season chronology of Blue Petrels, Thin-billed prions and Antarctic Prions from Kerguelen Islands. Larger dots mark more individuals starting or ending a phase on the same day. Note that Antarctic prions do not perform a continuous pre-laying exodus (e.g. see Electronic Supplement, Fig. S1), but the time bar here shows the length of the phase of alternating times at sea and in the colony.

**Table 2** Early breeding season chronology of Blue Petrels, Thin-billed prions and Antarctic Prions from Kerguelen Islands

| Dependent                  | Species   | Sex                  | Species:Sex interaction |
|----------------------------|-----------|----------------------|-------------------------|
| First arrival to colony    |           |                      |                         |
| Pre-exodus duration        |           |                      |                         |
| Departure on exodus        |           |                      |                         |
| Return from exodus         |           |                      |                         |
| Exodus duration            |           |                      |                         |
| Departure on incubation trip|          |                      |                         |
| Return from incubation trip|           |                      |                         |
| Incubation trip duration   |           |                      |                         |

Multifactorial ANOVA for the effects of species and sex on arrival dates and the timing and duration of the pre-laying exodus and the first incubation trip. Significant p-values are marked in bold.
Table 3 Timing of the early breeding season phases in Blue Petrels, Thin-billed prions and Antarctic Prions from Kerguelen Islands

|                      | Blue Petrel | Thin-billed prion | Antarctic Prion |

Multifactorial ANOVA were carried out with interactions. However, interactions were not statistically significant (all $P > 0.05$) and are therefore not given here.
The activity patterns also differed among the species, but not between the sexes (Table 4, Fig. 3). In particular, Blue petrels spent the least time (ca. 14 h) foraging, while Thin-billed prions foraged for nearly 18 h daily, including during about 6 h during the dark hours of night, dusk and dawn (Table 4). In contrast, Blue petrels spent much time in flight (9 h), compared to only 4 h in Thin-billed prions (Fig. 3).

The return dates from the exodus for egg-laying differed among the species, but not between the sexes (Table 2).

Incubation
The first incubation shifts were taken by the males, and consequently, the first incubation trips were carried out by the females, starting in October in Blue petrels, November in Thin-billed prions and December in Antarctic prions (Fig. 1, Fig. S1, Table 3). We observed species differences in the duration of the first incubation trip (Table 2), with shortest trips in Antarctic prions, intermediate trips in Thin-billed prions and longest trips in Blue petrels (Table 3).

The distribution during the first incubation trip varied latitudinally among the species (Fig. 2), with Blue petrels using more northerly latitudes than Thin-billed prions and Antarctic prions moved into easterly direction (Table 4, Fig. 2), while the distances reached did not differ consistently among the species.

The activity patterns also differed among the species, but not between the sexes (Table 5, Fig. 3). During the incubation trip, Blue petrels and Antarctic prions spent ca. 15 h foraging, while Thin-billed prions foraged for 17–18 h daily. In contrast, Blue petrels spent much time in sustained flight, compared to Thin-billed prions, while flight times were intermediate in Antarctic prions (Fig. 3).

Distribution and habitat parameters
The latitudinal distribution during the pre-laying exodus differed among the species (ANOVA, $F_{2,35} = 6.3$, $P = 0.004$), and Tukey Post-hoc tests indicated that Blue petrels used more northern latitudes than both Antarctic and Thin-billed prions (Fig. 2).

The latitudinal distribution during the first incubation trip also differed among the species (ANOVA, $F_{2,22} = 12.7$, $P < 0.001$), and Tukey Post-hoc tests here indicated that Antarctic prions used the most southern latitudes, while Blue petrels and Thin-billed prions did not differ statistically significantly (Fig. 2, $P = 0.075$).

Thus, between the winter and breeding seasons, the habitat preferences were reversed, with Antarctic prions changing from northern to southernmost, and Blue petrels in the opposite direction. Thin-billed prions were the most constant species in terms of latitudinal distribution.

Given the different distribution and timing during pre-incubation exodus and first incubation trips, this resulted in some differences in the habitat parameters.

Bathymetry from ECMWF ETOPO1 Elevation, Daytime SST and Chlorophyll a from MODIS Ocean Aqua OceanColor (4 km, 8 day mean), wind from ECMWF Interim Full Daily SFC Wind (10 m above Ground), wind speed was calculated from the square root of the sums of squares of the V and U component. Kruskal-Wallis ANOVAs were carried out for each parameter, to test for differences among the groups. All parameters differed ($\chi^2 > 17.9$, df = 5, $p < 0.003$), and similar superscript letters denote homogenous subsets

(Table 6). For example, Blue petrels tended to forage in the warmest, low productive waters (Fig. 4), and Antarctic prions experienced the most productive waters (Fig. 5 lower panel) and the calmest conditions with only light winds. When comparing the ecological niches based on these parameters, Antarctic Prions showed a large change between the winter and the breeding season, with 50% kernels of the PCs not overlapping (Fig. 4). In contrast, Blue petrels had largely overlapping seasonal niche spaces, and Thin-billed prions presented an intermediate case. These differences among the species were also seen in some single habitat parameters, especially sea surface temperature (Fig. 5, upper panel).

Stable isotope analyses
Isotopic data of whole blood from both sexes were pooled because they were not statistically significant, except $\delta^{15}N$ values of females and males blue petrels (Mann-Whitney, U = 12.0, $p = 0.035$). In early breeding, blood from the three species were segregated by their stable isotope values (MANOVA, Wilks’s Lambda, $F_{4,92} = 13.69$, $p < 0.0001$), with $\delta^{15}N$ values, but not $\delta^{13}C$ values, showing significant variations across species (ANOVA, $F_{2,47} = 28.95$ and 2.38, $p < 0.0001$ and $p = 0.104$, respectively) (Fig. 6, Fig. S2). Blood $\delta^{15}N$ values increased in the order 8.1 ± 0.2 % (AP, $n = 10$) < 8.9 ± 0.3 % (TBP, $n = 23$) < 9.3 ± 0.5 % (BP, $n = 17$) (post hoc Tukey’s HSD multiple comparison tests, all $p \leq 0.005$). Interestingly, the five birds with $\delta^{13}C$ values > -23.0 % were all males (one AP, two BP and two TBP, Fig. S2).

Discussion
In the present study, we explored the interplay of differences in timing of migration and the behaviour during the early breeding season. Using bio-logging data we found differences in colony attendance patterns among the three species, determined the foraging areas used during the pre-laying exodus and early incubation, and examined the activity data of tracked birds during the early breeding season. Stable isotopes completed the picture by confirming habitat changes between the inter-breeding and early breeding periods and highlighting resource segregation during the latter.

Ecological niches
Due to large differences in light and temperature throughout the year, polar environments are strongly seasonal. In marine environments, there is a succession of phytoplankton blooms and zooplankton reproduction and abundance throughout the spring and summer. Seabirds in Polar Regions have evolved different strategies to cope with these seasonal changes. Most polar birds are migratory, and thus move away from the breeding grounds. The three petrel species in this study have been shown to move to different latitudes and thus, environmental conditions, during the winter [13].

Migratory birds can employ either a ‘niche-tracking’ strategy, by moving to habitats with similar environmental conditions, or a ‘niche-switching’ strategy, with changing environmental conditions in the breeding and non-breeding season [39, 40]. While niche segregation within and among seabird species has received considerable attention lately (e.g. [8, 10, 13]), and other closely-related, sympatric seabird species have also been shown to adopt divergent migratory strategies [41] to our knowledge, the concept of ‘niche-tracking’ vs. ‘niche-switching’ has not been explored in seabirds.

Some care has to be taken in the terminology, as the term ‘niche-tracking’ has lately also been employed to explain shifts of populations in response to climate change [42]. The term ‘niche conservatism’, in contrast, is mostly used to compare niches in evolutionary time [43].

In the present study, Blue petrels spent the winter furthest south and returned earliest to start breeding. Although they used the most northern latitudes during the pre-laying exodus and incubation (Fig. 2), due to the early breeding schedule the water temperatures were still low and spring bloom had not started. Therefore, in terms of the ecological conditions, Blue petrels remained the most constant throughout the
year. By breeding early, they were able to track their preferred ecological niche in terms of oceanographic conditions. Comparison of $\delta^{13}C$ values between body feathers (corrected values) and blood confirmed that pattern with birds remaining within the Antarctic Zone during both the inter-breeding and early breeding periods, but using a more northern habitat during the latter period (Fig. 6).

In contrast, Antarctic prions spent the winter at the most northerly latitudes but during breeding, Antarctic prions used the most southern latitudes, resulting in a niche switch. This habitat switch is highlighted by stable isotopes, with birds showing more positive $\delta^{13}C$ values during the inter-breeding period than during the early breeding period, meaning a spatial change from subantarctic (subtropical)
waters to the Antarctic Zone (Fig. 6). Thin-billed prions were intermediate between the two strategies of niche tracking and niche switching, by remaining most faithful to their latitudinal distribution (Fig. 2) throughout the year. Accordingly, $\delta^{13}$C values of Thin-billed prions varied less than those of the other species. Birds remained within the Antarctic Zone, but foraged at slightly northern latitudes during the early breeding period than during the inter-breeding period (Fig. 6).

In songbirds, a common pattern is that of niche-tracking migrants and niche-switching residents [44, 45]. Hypotheses regarding the evolution of migration predict niche-tracking as primitive, and niche-switching as derived [33]. According to this, Antarctic prions would show the most derived state. According to genetic data [14], Blue petrels are ancestral, and Thin-billed prions and Antarctic prions are recently (0.9 Ma) derived sister taxa, fitting this pattern.

Another concept that was first developed in terrestrial birds [46, 47], and recently described in seabird ecology, is leapfrog migration, i.e. the case where northerly breeding species or populations migrate longer distances to spend the non-breeding season further south than southerly breeding populations or species. Leapfrog migratory populations have been found in Bulwer’s petrel Bulweria bulwerii [48], and the leapfrog concept has also been applied to sympatic Adélie and chinstrap penguins Pygoscelis adeliae and P. antarcticus [49]. The latter arises where two sympatic, central-place foraging colonial seabirds display a combination of allochrony and stage-dependent foraging ranges [49]. Allochrony is also found in the present study, with mean arrival dates among the species more than 1 month apart (Table 3, Figs. 1 and 2). Allochrony will result in a temporal offset of the peak energetic demands among the three petrels, such as previously shown for chick rearing sympatric Pygoscelid penguins [50] and for Brünnich’s and common guillemots Uria lomvia and U. aalge [51]. Although the patterns observed here suggest allochrony may result in avoidance of competition, further research may be needed to ascertain if competition is an important selective pressure upon the evolution of Blue petrel and prion phenology and migratory strategies. In contrast to penguins and auks, these petrels are highly mobile, and their early phenology may also have evolved to allow the three species to exploit different peaks in food availability following the spring bloom, and to complete the breeding and moult cycle prior to the onset of the Antarctic winter in species that remain in Antarctic waters (Blue petrels and Thin-billed prions).

**Activity data**

During the pre-laying exodus and the incubation trip, Thin-billed prions spent less time in constant flight and more time foraging (17–18 h) than Blue petrels and Antarctic prions (14–15 h, Fig. 3). This was not due to a shorter flight distance, as the maximum distance to the colony was shortest in Antarctic prions during the exodus (Table 4) and did not differ among the species during incubation (Table 5). Thus, differences in the activity patterns are most likely explained by differences in the foraging ecology, i.e. the diet choice or the search and handling time needed to feed on specific prey. The diet of the three species at Kerguelen has been studied in detail during the chick-rearing period [52, 53]. The dietary spectrum partly overlaps, but Blue petrels take considerably more fish (36% by mass) and less crustaceans (61%) than Thin-billed prions (6% fish, 91% crustaceans) and Antarctic prions (5% fish, 89% crustaceans). The most commonly taken crustacean was the hyperiid amphipod...
Themisto gaudichaudii, and the two prions were segregated by feeding on different euphausiids, Thin-billed prions on Thysanoessa spp. (16% by mass) and Antarctic prions on Euphausia vallentini (15% by mass). Antarctic prions also caught more small prey such as copepods than Thin-billed prions, which is probably related to filtering lamellae present in the beak of Antarctic prions. The diet in the early breeding season is not known, but it is likely that dietary differences would explain differences in the activity patterns observed here. Accordingly, blood δ¹⁵N values collected at GLS recovery and representing the pre-laying exodus time differed amongst the three species, thus showing trophic segregation. The higher δ¹⁵N value of Blue petrels is in agreement with the species preying more on mesopelagic fish during the breeding season, thus contrasting with the lower value of Antarctic prions suggesting a crustacean-based diet. Interestingly, the intermediate δ¹⁵N value of the Thin-billed prion suggests feeding partially on mesopelagic fish in early breeding, thus contrasting with the crustacean diet described during the chick-rearing and inter-breeding periods ([16, 52], Fig. 6).

Both sexes has largely similar daily activity budgets (Table 4). However, females spent more time sitting on the water. This resting time, together with the longer duration of the pre-laying exodus compared to males, may be important for the accumulation of nutrients for the egg.

Conclusions

We have shown that the three sympatric petrel species segregated in time and space, both in the winter as well as in the early breeding season. The interplay of timing and distribution meant that the three species show the full range of migratory strategies, from niche-tracking Blue petrels to niche-switching Antarctic prions. This meant that the habitat associations were partly reversed, and the latitudinal distribution resembled the leapfrogging of terrestrial avian migrant species or populations. More information on the diet taken during the different stages of the breeding cycle would be highly informative in order to explain differences in phenology and activity patterns, as the three species most likely exploit different peaks in food availability.
