Non Alcoholic Fatty Liver Disease in a Case of KABUKI Syndrome

Abstract
Kabuki syndrome (KS), a rare and relatively new syndrome, has been historically associated with classical facial dysmorphisms, heart and endocrine abnormalities, but only few cases of Kabuki syndrome with Glabnormalities have been reported. Congenital hepatic abnormalities, such as biliary atresia, neonatal sclerosing cholangitis, and idiopathic hepatic fibrosis, have been observed, but no case with Non alcoholic fatty liver disease (NAFLD) has been reported in literature.

Keywords: Kabuki Syndrome; Non Alcoholic Fatty Liver Disease; Fibrosis; Dysmorphism

Case
We present an interesting complication in an 8 y/o male child who has been following with our Pediatric Gastroenterology division for asymptomatic elevation of Liver enzymes. Patient was born full term via normal vaginal delivery but with significant congenital defects, notably complete cleft lip and palate, Imperforate anus and dysmorphic facies. Long palpebral fissures, everted lower eyelids, high arching eyebrows and flattened nasal bridge were characteristically consistent with findings expected in a patient with Kabuki Syndrome. He underwent colostomy while in the NICU, surgical repair at age of 8 months and Cleft repair at the age of 1 year of age. His infancy was complicated by hypoglycemia induced seizures at the age of 4 months, multiple ear infections and failure to thrive.

On the basis of facial dysmorphology, characteristic congenital defects, notably complete deft lip and palate, Imperforate anus and dysmorphic facies. Long palpebral fissures, everted lower eyelids, high arching eyebrows and flattened nasal bridge were characteristically consistent with findings expected in a patient with Kabuki Syndrome. He underwent colostomy while in the NICU, surgical repair at age of 8 months and Cleft repair at the age of 1 year of age. His infancy was complicated by hypoglycemia induced seizures at the age of 4 months, multiple ear infections and failure to thrive.

Subsequent serology trended over the next year, revealed persistently elevated Liver enzymes. Hepatic Ultrasound findings suggested an enlarged liver measuring 11.73 cm at the right mldavicular line. The hepatic parenchymal echogenicity homogeneously brightly increased and coarse with no visualization of the peripheral portal venous vasculature. There were no focal defects within the liver and there is no intra or extra hepatic biliary ductal ectasia. These findings of persistently elevated liver enzymes trended over a course of the year, specific hepatic ultrasound findings and a diagnostic Liver Biopsy was confirmatory for Fatty Liver disease, never reported in the past with kids of Kabuki Syndrome (Figure 1).

Figure 1: Liver Biopsy in the patient with KS showing fatty infiltration of the entire hepatic parenchyma.
Discussion

Kabuki "Make up" syndrome, a relatively new syndrome, first described in 1981 by 2 Japanese scientists [3-6], has been estimated to have an incidence of 1 in 32000 live births [7]. The diagnosis is usually made on the by seeing any four out of the following five characteristics in a patient: Characteristic facial features, Intellectual disability, short stature and endocrine abnormalities (Growth hormone commonly), Skeletal abnormalities (brachydactyly, dinoactyly, brachymesophalangy, vertebral abnormalities etc), dermatoglyphic abnormalities [7-9].

Other Multisystem abnormalities including, cardiovascular (Septal defects, Aortic arch disorders, conduction abnormalities) [9-14], Ophthalmological (coloboma, refractive errors), Immune disorders (ITP, Autoimmune hemolytic anemia, immune deficiency disorders), Hearing loss (conductive and sensori-neural) with variable percentages have been seen. For the great majority (55-80 percent) of children, chromosomal studies yield normal results [7]. Kabuki syndrome is caused by mutations in the KMT2D gene (also known as MLL2) or the KDM6A gene [1]. Miyake et al. [2] screened 81 patients with Kabuki syndrome for mutations in the MLL2 and KDM6A genes and identified MLL2 mutations in 50 (61.7%) and KDM6A mutations in 5 (6.2%).

GI abnormalities although in a small number; significantly contribute to the morbidity in these children. Biliary Atresia and gastro esophageal reflux are the most commonly reported gastrointestinal manifestations in this cohort [15-17]. NAFLD (non alcoholic fatty liver disease) which is currently a growing epidemic in the pediatric population can adversely affect the quality of life of such patients in addition to multiple health affecting a child with Kabuki Syndrome. Till date this phenotypic manifestation of patients with KS has not been reported. Castration of elevated liver enzymes secondary to the MLL or KMT2D gene needs to be researched further. The child reported. Causation of elevated liver enzymes secondary to the gastrointestinal manifestation of patients with KS has not been reported. Report of elevated liver enzymes secondary to the MLL or KMT2D gene needs to be researched further. The child continued to have clinically silent elevated liver enzymes and evidence of fatty infiltration on abdominal imaging, all this while thriving well, until the last follow up when the child was lost to follow up.
