Blueshifted galaxies in the Virgo cluster
I. D. Karachentsev, O. G. Nasonova (Kashibadze), Special Astrophysical Observatory, Russia

We consider a sample of 65 galaxies with negative radial velocities with respect to the Local group in the Virgo cluster. According to the Virgo Cluster Catalogue (=VCC, Binggeli et al., 1985), the population of the cluster accounts more than 2000 members, most of them are dwarf irregular (dIr), elliptical (dE) and spheroidal (dSph) systems. Assuming that Virgo distance is 17.0 Mpc (Tonry et al. 2001), dwarfs galaxies ($M_B < -16.5^m$) make up 80% of the sample. There is only one elliptical galaxy (NGC 4406) among 13 galaxies of normal and high luminosity.

Some features of the blueshifted galaxy sample

• All the blueshifted galaxies are distributed compactly within virial radius $\Theta_{VIR} = 6.0^\circ$.
• The centroid of the sample is displaced significantly at $V = 700 \pm 2500$ km/s.
• Galaxies of early and late types demonstrate an appreciable difference in their positioning relative to the centroid: E and S0 galaxies are located mainly at east side while objects with young stellar population tend to west and south sides.
• Surprisingly, dwarf galaxies of the sample (both early-type and late-type) exhibit a clumpiness on a scale of 10 arcmin ($\sim 50$ kpc). The median velocity difference in such pairs and triplets is about 70 km/s.

Conclusions

The observed NW asymmetry of the blueshifted galaxies may be interpreted as evidence for merging of the M86 subcluster with the main Virgo cluster body (Binggeli et al., 1993). A new attempt is made by us to explain this phenomenon by the tangential motion of the Local group regarding to the Virgo cluster caused by its pushing from the Local void.
