ABSTRACT
The circumgalactic medium (CGM) traced by $\text{O} \, \text{VI} \, \lambda \lambda 1031$, 1037 doublet absorption has been found to concentrate along the projected major and minor axes of the host galaxies. This suggests that $\text{O} \, \text{VI}$ traces accreting and outflowing gas, respectively, which are key components of the baryon cycle of galaxies. We investigate this further by examining the kinematics of 29 $\text{O} \, \text{VI}$ absorbers associated with galaxies at $0.13 < z_{\text{gal}} < 0.66$ as a function of galaxy color, inclination, and azimuthal angle. Each galaxy was imaged with the Hubble Space Telescope (HST), and the absorption was detected in COS/HST spectra of nearby ($D < 200$ kpc) background quasars. We use the pixel-velocity two-point correlation function to characterize the velocity spread of the absorbers, which is a method used previously for a sample of MgII absorber–galaxy pairs. The absorption velocity spread for $\text{O} \, \text{VI}$ is more extended than MgII, which suggests that the two ions trace differing components of the CGM. Again, in contrast to MgII, the $\text{O} \, \text{VI}$ absorption velocity spreads are similar regardless of galaxy color, inclination, and azimuthal angle. This indicates that the kinematics of the high-ionization gas is not strongly influenced by the current star formation activity in the galaxy. The kinematic homogeneity of $\text{O} \, \text{VI}$ absorption and its tendency to be observed mainly along the projected galaxy major and minor axes is likely due to varying ionization conditions and gas densities about the galaxy. Gas in intermediate azimuthal angles may be ionized out of the $\text{O} \, \text{VI}$ phase, possibly resulting in an azimuthal angle dependence of the distribution of gas in higher ionization states.

Key words: galaxies: halos – quasars: absorption lines

1. INTRODUCTION
The circumgalactic medium (CGM) is a massive reservoir of multiphase gas surrounding galaxies, with a gas mass comparable to the gas mass in the galaxies themselves (Thom et al. 2011; Tumlinson et al. 2011; Werk et al. 2013; Peeples et al. 2014). It regulates the star formation rate of galaxies through a balance of inflows and outflows into, out of, and through the CGM (e.g., Oppenheimer & Davé 2008; Lilly et al. 2013). For these reasons, understanding the multiphase nature, locations, and kinematic properties of gas in the CGM is crucial to understanding how galaxies evolve to form the galaxies observed today.

Much of the current understanding of the CGM comes from the low-ionization MgII $\lambda \lambda 2796, 2803$ doublet absorption in background quasar spectra because it is easily observable from the ground in optical wavelengths at $z \sim 1$. Recent work has found that MgII absorbers are preferentially located along the projected major and minor axes of their host galaxies (Bordoloi et al. 2011; Bouché et al. 2012; Kacprzak et al. 2012; Lan et al. 2014), and their kinematics show distinct differences with galaxy orientation, color, and other properties (Nielsen et al. 2015, 2016). MgII is commonly associated with outflows (e.g., Rubin et al. 2010, 2014; Bouché et al. 2012; Martin et al. 2012; Bordoloi et al. 2014a, 2014b; Kacprzak et al. 2014) and accretion or recycled outflows (e.g., Steidel et al. 2002; Kacprzak et al. 2010; Stewart et al. 2011; Martin et al. 2012; Rubin et al. 2012; Bouché et al. 2013; Ford et al. 2014).

However, given the multiphase nature of the CGM, MgII traces only a fraction of the CGM. The high-ionization $\text{O} \, \text{VI} \, \lambda \lambda 1031, 1037$ doublet absorption is another common tracer of the CGM. Tumlinson et al. (2011) has shown that the presence of $\text{O} \, \text{VI}$ is governed by the star formation rate of the host galaxy, with more absorbers associated with star-forming galaxies and more nonabsorbers with passive galaxies. $\text{O} \, \text{VI}$ has been further studied extensively (e.g., Wakker & Savage 2009; Prochaska et al. 2011; Johnson et al. 2013, 2015; Stocke et al. 2013; Mathes et al. 2014; Savage et al. 2014), but the physical processes giving rise to the gas traced by $\text{O} \, \text{VI}$ are still debated.

Recently, Oppenheimer et al. (2016) examined circumgalactic oxygen in the EAGLE simulations. They found that $\text{O} \, \text{VI}$ is not the dominant ionization state of oxygen in galaxy halos, and that the column densities of $\text{O} \, \text{VI}$ peak for $L_*$ galaxies, with lower column densities for lower and higher mass halos. Based on this, the authors suggest that $\text{O} \, \text{VI}$ is primarily a tracer of the virial temperature of a galaxy, where $L_*$ galaxies have a virial temperature that results in the largest $\text{O} \, \text{VI}$ ionization fraction. For galaxies less massive than an $L_*$ galaxy, the virial temperature is too cool for strong $\text{O} \, \text{VI}$, and more massive galaxies ionize the oxygen into higher ionization states. The authors also found no connection between star formation and the $\text{O} \, \text{VI}$ out to 150 kpc, where the median “age” of $\text{O} \, \text{VI}$ is greater than 5 Gyr. Consequently, the Tumlinson et al. (2011) results may be reflecting the changing ionization conditions with galaxy mass rather than a star formation rate dependence.

It has become more common to compare the properties of and the processes that deposit both the low-ionization gas traced by MgII and the high-ionization gas traced by $\text{O} \, \text{VI}$. For example, Muzahid et al. (2015) studied an absorber–galaxy pair...
in detail, where the pair has both Mg II and O VI absorption probed along the minor axis of an edge-on galaxy. The authors concluded that the low- and high-ionization absorption traced recycled accretion and outflows, respectively. The metallicities of the ions are different, with the high-ionization phase having a metallicity (super-solar) over an order of magnitude greater than the low-ionization phase.

Using mock quasar absorption-line observations in hydrodynamic cosmological simulations, Churchill et al. (2015) examined the properties of the multiphase gas in the CGM of a dwarf galaxy. The authors traced the line-of-sight spatial locations of the cells that dominate the absorption profiles. They found that while C IV and O VI are observed at similar velocities as H I and Mg II, the higher ionization gas traces different structures in different locations (spread over up to 100 kpc) along the line of sight. Also studying the simulated CGM, Ford et al. (2014) found that O VI primarily traces "ancient outflows" in which the gas was ejected from galaxies by outflows greater than 1 Gyr before \( z = 0.25 \). In contrast, they found that Mg II is dominated by recycled accretion.

Kacprzak et al. (2015) measured the orientations (inclinations and azimuthal angles) of galaxies associated with both O VI absorbers and nonabsorbers. They define an azimuthal angle of \( \Phi = 0^\circ \) as having the background quasar sightline aligned with the projected galaxy major axis, and \( \Phi = 90^\circ \) as the sightline along the projected galaxy minor axis. The authors reported that detected O VI absorption is preferentially found along the major and minor axes of the host galaxy (similar to the behavior of Mg II; Kacprzak et al. 2012), suggesting that the absorbers in these regions traced accretion or recycling, and outflows, respectively. Absorption was rarely detected within azimuthal angles of \( 30^\circ \text{--} 60^\circ \), with the authors proposing that O VI is not mixed throughout the CGM. The equivalent widths of absorption were also found to be greater along the minor axis than the major axis, which suggests that the velocity spreads, the column densities, or both were dependent on the azimuthal angle at which gas is probed. To further examine the physics involved and the gas properties in relation to the host galaxies, we study the kinematics of these O VI absorbers here.

Nielsen et al. (2016) and Nielsen et al. (2015) (hereafter MAGiCAT IV and MAGiCAT V, respectively) both used the pixel-velocity two-point correlation function (TPCF) method for Mg II absorbers to examine the velocity spreads as a function of galaxy color, redshift, impact parameter, inclination, and azimuthal angle. The TPCF method produced clear results in which the greatest absorber velocity dispersions were located along the projected minor axis (\( \Phi \gtrsim 45^\circ \)) of face-on \((i < 57^\circ)\) blue galaxies. These large velocity dispersions were attributed to bipolar outflows, which, for the largest velocity dispersions, are pointed nearly directly toward or away from the observer. Red galaxies did not show these large dispersions, and in fact, showed the smallest velocity dispersions out of all subsamples, indicating a lack of outflowing material in Mg II.

In this paper, we now use this TPCF method on a sample of 29 O VI absorbing galaxies as a function of galaxy color, inclination, and azimuthal angle. We also compare the O VI TPCFs to the previous results with Mg II.

This paper is organized as follows: Section 2 describes the O VI sample and data analysis to obtain galaxy and absorption properties. We also briefly describe the pixel-velocity TPCF method. Section 3 presents the results of examining the TPCFs of O VI absorbers as a function of galaxy color, azimuthal angle, and inclination. We also present the TPCFs for our Mg II sample (MAGiCAT IV and V) in this section for comparison between ions. In Section 4 we discuss our results in the context of previous work. Finally, Section 5 summarizes and concludes our findings. Throughout the paper we use AB magnitudes and a \( \Lambda \)CDM cosmology (\( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}, \Omega_M = 0.3, \Omega_\Lambda = 0.7 \)).

2. SAMPLE AND DATA ANALYSIS

In this section, we describe the galaxy properties and the quasar spectra for our O VI absorber--galaxy sample, which is the focus of this paper. We also briefly describe the Mg II sample published in MAGiCAT IV and V, which we use here for comparison to the more highly ionized O VI CGM. Finally, we briefly describe our pixel-velocity TPCF method for studying the absorption kinematics.

2.1. Galaxy Properties

We use the subset of 29 galaxies with colors and detected O VI \( \lambda\lambda1031, 1037 \) doublet absorption from the sample presented in Kacprzak et al. (2015) (hereafter Kacprzak15), which were identified as part of our “Multiphase Galaxy Halos” large Hubble Space Telescope (HST) program (e.g., Kacprzak15, Muzahid et al. 2015, 2016) or obtained from the literature. The galaxies with non-detections in O VI reported in Kacprzak15 are not included here as we cannot measure their absorption kinematics. The absorption-selected galaxies are located at spectroscopic redshifts of \( 0.13 < z_{\text{gal}} < 0.66 \) (median \( z_{\text{gal}} = 0.244 \)) and within an on-the-sky projected distance of \( D \sim 200 \) kpc \((21.1 \text{ kpc} < D < 203.2 \text{ kpc}, \langle D \rangle = 93.2 \text{ kpc})\) from a background quasar. These are isolated galaxies, where no neighbors were identified within a projected distance of 200 kpc from the quasar line of sight and within a line-of-sight velocity separation of 500 km s\(^{-1}\).

We slightly modified the Kacprzak15 sample in a few cases. The sample we use is summarized in Table 1, and the changes are as follows. The J121920 absorber--galaxy pair is excluded here because the azimuthal angle measurement is highly uncertain. We calculated galaxy colors for two additional galaxies using magnitudes obtained from NED\(^5\): J100402 \((u - r = 1.00)\) and J111908 \((B - K = 2.21)\). Lastly, the colors quoted by Kacprzak15 for the J045608 galaxies are transposed in their Table 2; the values are published correctly in Nielsen et al. (2013b).

After follow-up observations with ESI/Keck spectra, we found that the impact parameters of the two J1233--0031 galaxies \((z_{\text{gal}} = 0.4174 \text{ and } z_{\text{gal}} = 0.3185)\) reported by Werk et al. (2012) appear to be transposed. The \( z_{\text{gal}} = 0.3185 \) galaxy, which is included here, is located at \( D = 85 \) kpc rather than \( D = 31 \) kpc. This error is propagated in Kacprzak15, and the reported inclination and azimuthal angle measurements should be \( i = 38.7^\circ \text{ and } \Phi = 17.0^\circ \), respectively. This does not significantly change their results, however. We also later found that one of the galaxies listed in the Kacprzak15 sample is located in a group environment: Q0122--003, \( z_{\text{gal}} = 0.3787 \), with a neighboring galaxy at \( z_{\text{gal}} = 0.3792 \). It is also listed in the MAGiCAT sample as an isolated galaxy, although we do not have a HIRES or UVES quasar spectrum for the associated absorber, therefore it is not included in the MAGiCAT IV or V

\(5\) https://ned.ipac.caltech.edu/
analyses. For the work presented here, we do not use this galaxy and have moved it to a group sample for later analysis.

Each of the 29 galaxies in our sample was imaged with WFPC2, WFC3, or ACS on the HST and their morphological properties were modeled using GIM2D (Simard et al. 2002). Full details of the galaxies and their modeling are described in Kacprzak15. We define an inclination of $i = 0^\circ$ as face-on and $i = 90^\circ$ as edge-on. An azimuthal angle of $\phi = 0^\circ$ indicates that the background quasar sightline is aligned with the projected galaxy major axis, and $\phi = 90^\circ$ indicates the sightline is aligned with the projected galaxy minor axis.

Galaxy $u - r$ colors from Kacprzak15, plus an additional $u - r$ color obtained from NED, were converted into $B - K$ colors following similar methods described in Nielsen et al. (2013b, MAGITCAT I) for direct comparison to the Mg II sample studied in MAGITCAT IV and V, which uses $B - K$ colors. Colors for each galaxy spectral energy distribution (SED) were calculated, and we obtained a linear least-squares fit of $(B - K) = 1.10(u - r) + 0.113$ to the galaxy SED colors. We then applied this relation to the $u - r$ colors to have a uniform set of $B - K$ colors, and the new values are listed in Table 1.

In order to examine the absorber kinematics for galaxies as a function of different baryon cycle processes and star formation rates, we form various subsamples by using the median galaxy property values of the sample. For the orientation measurements, these values are $(i) = 51^\circ$ and $(\phi) = 45^\circ$. Using the average inclination of galaxies in the universe, as was done in MAGITCAT V, is not feasible here because the subsample sizes with that cut would not be balanced. The uncertainties on the orientation measurements are small enough such that only one galaxy could potentially shift from being assigned to the minor axis subsample to being assigned to the major axis subsample, and only two galaxies could shift from face-on to edge-on.

The median galaxy color of the sample is $(B - K) = 1.66$. This value is used to compare between galaxies that are more likely to be star-forming or passive rather than with galaxy morphological types or with the color bimodality of galaxies in the universe. Comparing the absorption associated with blue galaxies to that associated with red galaxies is important because previous work has shown that the equivalent widths (which depend on the velocity width and column density of the gas) of low-ionization Mg II absorbers depend on some measure of the star formation rate (e.g., Zibetti et al. 2007; Bordoloi et al. 2011; Rubin et al. 2014). Tumlinson et al. (2011) found that O VI, which is the focus here, also depends on the SFR of the host galaxy, where star-forming galaxies nearly always have detected absorption and passive galaxies rarely have detected absorption. Since we do not currently have star formation rates, we rely on galaxy color as a proxy for comparison to the Tumlinson sample.

The cut used here, $(B - K) = 1.66$, is roughly consistent with the boundary between star-forming O VI absorbing galaxies and passive O VI non-absorbing galaxies. Kacprzak15 show that the boundary between mostly O VI absorbing and mostly O VI non-absorbing galaxies is roughly at $B - K = 1.6$ (same for $u - r$). While Kacprzak15 do not have the star formation rates of the galaxies, this cut is consistent with Tumlinson et al. (2011).

The subsample cuts, median redshift, and number of galaxies in each subsample are listed in Table 2. We also list the subsample cuts for the Mg II subsamples from MAGITCAT IV and V for comparison.

There are no significant correlations between galaxy properties in the sample. There are also no biases with azimuthal angle or inclination; a one-dimensional Kolmogorov–Smirnov test reports that the azimuthal angles and inclinations of the galaxies are consistent with unbiased samples at the 0.6 $\sigma$ and 2.6 $\sigma$ levels, respectively.

### 2.2. Quasar Spectra

The galaxies described in the previous section are associated with absorption in 23 quasars. Each quasar has a medium resolution ($R \sim 20,000$, FWHM $\sim 18$ km s$^{-1}$) spectrum from COS/HST, which covers the detected O VI $\lambda\lambda 1031$, 1037 doublet at the redshifts of the targeted galaxies. Full details of the spectra, their reduction, and the modeling of absorption are listed in Kacprzak15. Each O VI $\lambda\lambda 1031$, 1037 doublet was Voigt profile (VP), fitted, simultaneously when possible to account for blends, using VPFIT.\(^6\) Velocity zero-points (i.e., $z_{\text{abs}}$) were defined as the median velocity of the optical depth distribution of absorption for the O VI $\lambda 1031$ line. The O VI absorption doublets for the absorber–galaxy pairs are plotted in Figure 1.

The velocity range of each absorber was determined by finding the velocity or wavelength at which the VP model spectrum (rather than the actual spectrum) decreases by 1% from the continuum level. The VP model is used to define the velocity ranges because several O VI absorbers are blended

\(^6\) http://www.ast.cam.ac.uk/~rfc/vpfit.html
with other ions and the spectra are more noisy than the HIRES or UVES spectra for Mg II. For our analysis, we use only those pixels that are located within these velocity bounds, which are plotted as gray shaded regions in the $\lambda 1031$ panels of Figure 1.

This method is simpler than the method used for Mg II because the OVI absorbers have a less complex absorption profile; the OVI absorbers generally consist of a single broad “kinematic subsystem”, while Mg II may be composed of multiple kinematic subsystems (e.g., Churchill & Vogt 2001, MAGiICAT IV, V). Only one OVI absorber (J121920) has two kinematic subsystems, but we exclude this absorber from our analysis because the associated galaxy has a highly uncertain azimuthal angle measurement. When we use this velocity range determination method on the MgII absorbers from MAGiICAT Figure 1.

### Figure 1.

OVI $\lambda 1031, 1037$ doublet absorption profiles and fits for each absorber–galaxy pair in the sample. In each panel pair, the $\lambda 1031$ line is plotted at the top, and the $\lambda 1037$ line at the bottom. The quasar spectrum is plotted as the black histogram, the uncertainty on the spectrum is the green line, and the fit to the data is plotted as the red line. Vertical red ticks at the top of each panel show the central velocity of each Voigt profile component fitted to the data. Gray shaded regions in the top panels indicate the velocity range of the absorbers, defined in Section 2.2. For the TPCF calculations, we use only those pixels that are located within these shaded regions. Velocity zero-points are defined as the optical depth-weighted median of the absorption.

The Astrophysical Journal, 834:148 (12pp), 2017 January 10
Nielsen et al.
IV and V, we find comparable, or more conservative ranges (i.e., velocities closer to $v = 0 \text{ km s}^{-1}$) than with our previous method in nearly all cases. Thus, the different methods do not produce drastically different results, and our simpler method may slightly underestimate the velocity extents of the OVI kinematics compared to MgII.

2.3. The MgII Comparison Sample

We compare the OVI absorber kinematics to the MgII absorber kinematics published in MAGiCAT IV and V. Here we briefly describe the MgII sample and refer to the MAGiT CAT series papers for further details (Churchill et al. 2013; Nielsen et al. 2013a, 2013b, 2015, 2016).

We use a subset of 30 absorber–galaxy pairs with MgII absorption from the MgII Absorber–Galaxy Catalog (MAGIICAT). All of these galaxies have spectroscopic redshifts ($0.3 < z_{\text{gal}} < 1.0$, $\langle z_{\text{gal}} \rangle = 0.656$), $B - K$ colors ($\langle B - K \rangle = 1.4$), and MgII absorption detected in high-resolution background quasar spectra (HIRES/Keck or UVES/VLT) within a projected distance of $D = 200 \text{ kpc}$ ($\langle D \rangle = 40 \text{ kpc}$). Additionally, all
galaxies have \textit{HST} images with which the orientations have been measured using \textsc{gim2d} (Kacprzak et al. 2011b, 2012). Of the 30 Mg II absorber–galaxy pairs, only seven have associated O \textsc{vi} absorption and overlap with the O \textsc{vi} sample presented in Section 2.1. We note that the absorber–galaxy pairs in this MAGITCAT sample have higher redshifts, bluer colors, and smaller impact parameters on average than our main O \textsc{vi} sample.

Subsamples for the Mg II sample are determined by the median galaxy color of \((B - K) = 1.4\), as well as orientation measurements of \(i = 57^\circ\) (the mean inclination of galaxies in the universe), and \(\Phi = 45^\circ\). These values and the subsample sizes are tabulated in Table 2 and are further described in MAGITCAT IV and V.

The absorption kinematics for the Mg II sample have been fully analyzed in MAGITCAT IV and V. We present these kinematics here for comparison, but do not report any new results.

2.4. Pixel-velocity TPCFs

To examine the absorber kinematics as a function of galaxy properties, we use the pixel-velocity TPCF method described in detail in MAGITCAT IV and V. A summary of the method follows.

The pixel-velocity TPCF is calculated by first obtaining the velocities of all pixels within the velocity bounds of detected absorption for a subsample. A velocity of \(\nu = 0\) km s\(^{-1}\) corresponds to the optical depth-weighted median of absorption and defines the absorption redshift, \(z_{\text{obs}}\). The pixel velocities for all absorbers in a subsample are pooled together as if they came from a single absorber hosted by a galaxy of a certain type, e.g., blue galaxies probed along the projected minor axis. Velocity separations between each pixel pair, without duplications, are then calculated for this pool. The absolute values of these velocity separations are then binned into 20 km \(s^{-1}\) wide bins, which is comparable to the FWHM of COS/\textit{HST}. The count in each bin is normalized by the total number of pixel-velocity pairs in the subsample to account for varying subsample sizes when comparing between subsamples. The pixel-velocity TPCF is thus a probability distribution function and provides a statistical view of the absorber velocity dispersion for a given galaxy subsample.

Uncertainties in the TPCFs are calculated using a bootstrap analysis with 100 realizations. The uncertainties reported are 1\(\sigma\) deviations from the mean of the bootstrap realizations, which allow for asymmetrical uncertainties around the true TPCFs.

To compare TPCFs between subsamples, we perform a chi-squared test, taking into account the uncertainties in the TPCFs. We also report \(\Delta \nu(50)\) and \(\Delta \nu(90)\) values for each TPCF, i.e., the velocity separation within which 50\% and 90\% of the area below the TPCF curve is contained, to help describe where two TPCFs differ in more detail than the chi-squared test provides. These values are tabulated in Table 2. The uncertainties on \(\Delta \nu(50)\) and \(\Delta \nu(90)\) are calculated from the bootstrap realizations, similar to the TPCF uncertainties.

The bin sizes for the TPCFs presented here are twice as large as the TPCFs presented with Mg II (MAGITCAT IV and V) because the COS spectra have a coarser spectral resolution than HIRES spectra. To test the effect that changing the TPCF bin sizes had, we reran the Mg II TPCFs from MAGITCAT IV and V with the 20 km \(s^{-1}\) bin widths. With larger bin sizes, the general Mg II TPCF results remained unchanged. These coarser Mg II TPCFs are presented with the O \textsc{vi} TPCFs for comparison between ions.
Figure 3. Pixel-velocity TPCFs for the full samples of 29 O VI and 30 Mg II absorbers with the same binning for comparison between ions. The Mg II absorbers come from MAGiCAT IV and include only those absorber–galaxy pairs with galaxy colors and orientation measurements. The thick purple line and shading indicate O VI TPCFs and uncertainties, respectively, while the thin orange line and shading represent Mg II. O VI absorbers have significantly larger velocity dispersions than Mg II absorbers.

3. RESULTS

3.1. Full Sample

3.1.1. Sample Distribution

The distribution of both O VI and Mg II absorbers as a function of their orientation relative to the host galaxy is plotted in Figure 2. Panel (a) presents the azimuthal angle versus impact parameter of each absorber–galaxy pair. The galaxy for each pair is located at \( D = 0 \) kpc, with the major axis aligned with \( \Phi = 0^\circ \). Points represent the location of the background quasar sightline. Point sizes indicate the velocity width of absorption, i.e., the difference between the extremes of the gray shaded regions in Figure 1. Point sizes can be compared between ions as both are normalized to the maximum velocity spread of the O VI absorbers.

There is an overlap of seven absorber–galaxy pairs between the Mg II and O VI samples. These are presented as orange points on top of purple. We note that although the overlapping points (the differing ions) are plotted in the same locations, their \( z_{\text{abs}} \) values can differ by up to roughly 110 km s\(^{-1}\) (for the Mg II profiles, see Kacprzak et al. 2011b). The smallest velocity separation between the \( z_{\text{abs}} \) for the two ions is 27 km s\(^{-1}\). Given that \( z_{\text{abs}} \) is the optical depth-weighted median of absorption, this indicates that the absorption is distributed differently along the line of sight between the two ions.

The azimuthal behavior of the samples discussed in detail by Kacprzak et al. (2012) (Mg II) and Kacprzak15 (O VI) appears to be present in this plot, although the trend is less obvious here. This is likely because we only present a subset of

**Notes.**

* The Mg II data, analysis, results, and conclusions are published in Nielsen et al. (2015) and Nielsen et al. (2016), and references therein.

* km s\(^{-1}\).

* Values listed are for Mg II absorbers.
the Mg II sample studied by Kacprzak et al. (2012). There is a population of absorbers for both ions within $\Phi \sim 15^\circ$ of the major axis, a slight gap, and then another larger population at $\Phi > 35^\circ$. Interestingly, the group of three O VI absorbers located at $D \sim 140$ kpc and $30^\circ < \Phi < 45^\circ$ appear to have smaller point sizes than the rest of the O VI absorbers. As shown in Kacprzak15, the frequency of “non-detections” in O VI ($W_r(1031) < 0.1$ Å) is highest between $30^\circ < \Phi < 60^\circ$. In fact, these three points have $W_r(1031) < 0.1$ Å, the only absorbers with equivalent widths this low in the sample presented here. We refrain from investigating the azimuthal angle distribution preferences of the absorbers further as these were examined previously.

Figure 2(b) presents the impact parameter, $D$, as a function of inclination, $i$, for the Mg II and O VI samples. Point sizes again represent the velocity width of absorption. The vertical dashed lines represent the inclinations by which we divide the sample into “face-on” ($i \sim 0^\circ$) and “edge-on” ($i \sim 90^\circ$) subsamples. For the Mg II sample, we used the mean inclination of the O VI absorbers to even out subsample sizes. The Mg II absorbers appear to have a larger variation in their point sizes (velocity spreads) than O VI, but this is only a subtle difference. The dependence of the point sizes on $\Phi$, $i$, and $D$ is also difficult to discern. We use the pixel-velocity TPCFs to examine these differences in more detail below.

### 3.1.2. Pixel-velocity TPCFs

As a first comparison of the kinematics between the different ions, the TPCF for the full sample of O VI absorbers is plotted in Figure 3 as a thick purple line with shading that represents the errors. The full sample of Mg II absorbers with the same binning is plotted as the thin orange line with shading that represents the errors. The velocity dispersion of O VI tends to be large, with pixel-velocity separations up to ~400 km s$^{-1}$. This is in contrast to the more narrow Mg II TPCF. Compared to Mg II, $\Delta v(50)$ and $\Delta v(90)$ for O VI are roughly 50% and 40% larger, respectively.

It is important to keep in mind that our O VI sample of galaxies is located at lower redshifts ($\langle z_{gal} \rangle = 0.244$), is probed at greater distances on average ($\langle D \rangle = 93.2$ kpc, as shown in Figure 2), and has redder colors ($B - K = 1.66$) than the Mg II galaxies. We discuss these differences in Section 4. For easy comparison between the two ions, the subsample cuts and sizes for each ion are listed in Table 2 for the rest of the presented results.

### 3.2. Color and Orientation

The TPCFs of blue galaxies (panel (a)) and red galaxies (panel (b)) probed along the projected major and minor axes are plotted in Figure 4. There are no differences in the O VI TPCFs for either panel (0.1$\sigma$ and 0.4$\sigma$), and $\Delta v(50)$ and $\Delta v(90)$ for each subsample pair are all consistent within uncertainties. For the subsample pairs not shown, the chi-squared results are 0.1$\sigma$ (major axis, blue versus red galaxies) and 0.4$\sigma$ (minor axis, blue versus red galaxies). The slightly (but not significantly) larger velocity separation tail for red galaxies in Figure 4(b) is due to a single absorber with $W_r(1031) = 0.817$ Å, which is an outlier in equivalent width for the sample. This unusually strong O VI equivalent width absorber was studied in detail by Muzahid et al. (2015), who associated the absorption with a large-scale outflow. Removing this absorber does not change the conclusions drawn from the TPCFs. The TPCFs of the Mg II absorbers for the same subsamples (MAGiCat V, inset panels) are comparatively more narrow, with the exception of the blue, minor axis subsample in panel (a), which has a velocity dispersion similar to the O VI.

For the TPCFs in Figure 5, which compare face-on and edge-on inclinations for blue galaxies (panel (a)) and red galaxies (panel (b)), there are again no differences in the velocity dispersions for each subsample pair ($\sim 0$ $\sigma$ for all pairs). The $\Delta v(50)$ and $\Delta v(90)$ are all consistent within uncertainties, and the conclusions do not change when the large equivalent width absorber is removed.

![Figure 4](image-url)
from the sample. In comparison, while the Mg II TPCFs (published in MAGIICAT V, inset panels) for edge-on subsamples are consistent within uncertainties, similar to the behavior of O VI, they have smaller velocity dispersions than O VI. While the Mg II TPCF for the red, face-on galaxy subsample is also much more narrow than O VI, the Mg II TPCF for the blue, face-on galaxy subsample is comparable to O VI, the rest have smaller dispersions.

3.3. Inclination and Azimuthal Angle

For face-on galaxies in Figure 6(a), we find no differences (0.7σ) in the O VI TPCFs for galaxies probed along the projected major or minor axes. The Δν(50) and Δν(90) are consistent within uncertainties. This is in contrast to the Mg II results from MAGIICAT V (inset panels), where face-on, major axis galaxies host absorbers with much smaller velocity dispersions. The face-on, minor axis Mg II TPCF is comparable to the O VI TPCF.

Conversely, we find significant differences in the O VI TPCFs for edge-on galaxies probed along the major and minor axes in Figure 6(b). Galaxies probed along the minor axis have larger velocity dispersions than those along the major axis, corresponding to a 4.6σ significance. This significance drops to 3.4σ when the outlier in O VI equivalent width is removed from the sample, and this remaining marginally significant difference is due to a combination of small uncertainties on the minor axis subsample and the major axis being slightly less extended than the rest of the subsamples.
$W_1(1031) = 0.817 \, \text{Å}$ absorber (an edge-on, minor axis galaxy; Muzahid et al. 2015); however, removing the absorber from the sample still results in a significance of $3.4\sigma$, although the scatter on the edge-on, minor axis subsample is significantly reduced. This result is in contrast to our previously published results with Mg II (MAGIICAT IV and V, inset panels), which have TPCFs consistent within uncertainties. The edge-on, major axis subsample for O VI is comparable to the Mg II subsamples.

For face-on and edge-on galaxies probed along the major axis (not plotted), we find an insignificant difference of $2.5\sigma$ where face-on galaxies tend to have a slightly larger velocity spread than edge-on galaxies. This behavior is opposite to what we found in Mg II (MAGIICAT V), although the edge-on Mg II subsample has a velocity dispersion comparable to the same O VI subsample.

Finally, for galaxies probed along the minor axis (not plotted), we find a significant difference ($4.0\sigma$) between the TPCFs of face-on and edge-on galaxies, where absorbers hosted by edge-on galaxies tend to have larger velocity spreads. However, the significance decreases to $0.9\sigma$ when we remove the outlying $W_1(1031) = 0.8 \, \text{Å}$ absorber. This behavior is also opposite to what we found with Mg II. As stated above, the Mg II face-on, minor axis subsample is comparable to O VI.

As we showed in the previous paragraphs, removing the outlying large equivalent width absorber does not change the results in one comparison (Figure 6(b)), but removes the significant difference in another (minor axis, face-on versus edge-on subsamples). This results from the combination that the edge-on, major axis subsample TPCF is slightly more narrow than the rest of the subsamples, but the uncertainties are large enough to overlap with the face-on subsamples, and that the uncertainties on the edge-on, minor axis subsample are reduced when the outlier is removed. Given this and the fact that the remaining significance of $3.4\sigma$ is marginally significant (certainly not at the levels found with most Mg II comparisons), we make the assumption that there are no kinematic differences between these subsamples when the outlying large equivalent width absorber is excluded.

4. DISCUSSION

As we have shown in the previous sections, the kinematics of O VI absorbers are similar regardless of galaxy color, azimuthal angle, and inclination. Compared to our previously published Mg II TPCFs (MAGIICAT IV and V), the O VI TPCFs are more extended and are much less sensitive to the galaxy properties. In subsamples where we expect outflows to dominate the absorption, Mg II and O VI TPCFs are comparable.

The velocity spreads are larger for O VI than for Mg II for nearly all subsamples. This may be explained if O VI is collisionally ionized, where OVI absorption profiles would be broader than Mg II. However, the contrasts between the two ion samples still seem puzzling. If the two ions trace the same gas, then the relative behavior of the TPCFs between the ions should be similar as they are the result of the same baryon cycle processes, i.e., in Figure 5(a), the face-on subsample should be more extended than the edge-on subsample for both O VI and Mg II, but this is not the case. If we assume that this scenario is true (we show below that this is probably not the case), we can examine the several differences between the two samples that may be contributing to our TPCF results.

The O VI sample probes the CGM at larger impact parameters on average ($\langle D \rangle = 86 \, \text{kpc}$) than the Mg II sample ($\langle D \rangle = 40 \, \text{kpc}$; see Figure 2; MAGIICAT IV and V). Simulations by Oppenheimer et al. (2016) show an age–radius anticorrelation with O VI absorption, where the time since gas was ejected from a galaxy through outflows increases with increasing radii. The lack of a kinematic dependence on orientation in the O VI sample TPCFs may then be a result of the absorbers being located farther away from the galaxies, and thus less dependent on the current star formation activity than for the Mg II sample. This is strengthened by the finding that the O VI TPCFs show similar behaviors for both blue and red galaxies.

The galaxies hosting O VI absorbers tend to be redder than Mg II host galaxies, with $\langle B - K \rangle = 1.66$ and $\langle B - K \rangle = 1.4$, respectively. For Mg II, the kinematics of absorbers around redder galaxies are less sensitive to the orientation at which they are located than they are for blue galaxies (for example, see the inset TPCFs in Figures 4 and 5; also see MAGIICAT V). Additionally, redder galaxies tend to have lower star formation rates, and consequently are not expected to have active outflows or accretion. Given this, we would expect less of an orientation dependence for the O VI absorbers because they are redder galaxies on average than the Mg II sample, which does show an orientation dependence.

The redshift distributions of the two samples are also different. While the galaxies for the Mg II sample were located at a median redshift of $\langle z_{\text{gal}} \rangle = 0.656$ ($0.3 < z_{\text{gal}} < 1.0$), the O VI sample has a median of $\langle z_{\text{gal}} \rangle = 0.244$ ($0.1 < z_{\text{gal}} < 0.66$). In this case, the lower redshift galaxies have lower star formation rates (they tend to be redder), and thus have a less active baryon cycle than at higher redshifts. This would result in a weaker dependence of the absorber kinematics on galaxy orientation for the lower redshift O VI sample. Kacprzak et al. (2011a) reported the fraction of systems where Mg II absorption velocities were in alignment with the host galaxy rotation direction. They found that this fraction decreases by a factor of two from $z \sim 0.5$ to $z \sim 0.1$. Furthermore, they report an increase of a factor of three at $z \sim 0.1$ compared to $z \sim 0.5$ for Mg II absorption spanning both sides of the host galaxy systemic velocity. It is possible that CGM kinematics may evolve with redshift; however, we have yet to explore the Mg II TPCFs in the lower redshift range probed by the O VI sample because of the lack of high-resolution spectra.

While the differences between the two samples listed above probably do have some effect on our results, they probably do not dominate. The discussion above mostly assumes that O VI and Mg II trace the same components of the CGM. However, it is more likely that with their differing ionization states and kinematics, the two ions trace different components of the CGM. This is supported by both observations (e.g., Werk et al. 2013; Muzahid et al. 2015) and simulations (e.g., Ford et al. 2014; Churchill et al. 2015). Even for the overlapping seven galaxies in the Mg II and O VI samples with absorption in both ions, the two ions are offset in $z_{\text{abs}}$ (defined as the optical depth-weighted median of the absorption) by as little as $\sim 10 \, \text{km s}^{-1}$ or as great as $\sim 100 \, \text{km s}^{-1}$. These seven absorbers show that the distribution of the gas is different in velocity space between ions.

Using roughly the same sample we use here, Kacprzak15 showed that O VI absorption is preferentially distributed along the major and minor axes of the host galaxies, with non-
detected O VI sightlines primarily located between the major and minor axes. The authors suggested that O VI is not mixed throughout the CGM and is confined into outflows along the minor axis and inflows or recycled gas along the major axis. They also showed that the O VI equivalent widths were stronger along the projected minor axis than along the major axis, suggesting that either the column densities, the velocity spreads, or both are larger for absorbers located along the minor axis. These results seem to contradict what we find here with the kinematics.

Since the kinematics of the O VI absorbers are roughly consistent for all galaxy color and orientation combinations, this suggests that O VI may not trace different baryon cycle processes. In simulations, Ford et al. (2014) found that O VI traces gas that was ejected from galaxies by ancient outflows many Gyr prior to the current epoch, some of which is likely re-accreting onto the galaxies at the time of the mock observations. If this is the case, then the absorbing gas may have abundant time to mix and form a roughly kinematically uniform O VI halo at all locations about galaxies. The sizes of O VI absorbers are also predicted to be large, on the order of tens to hundreds of kiloparsecs from photoionization modeling (Lopez et al. 2007; Muzahid et al. 2014; Hussain et al. 2015), so that any kinematic differences with galaxy orientation may be wiped out by the large cloud sizes. This is in contrast to the small ~10 pc cloud sizes expected for Mg II (e.g., Rigby et al. 2002; Crichton et al. 2015). A kinematically uniform O VI halo is therefore reasonable. The combination of consistent absorber kinematics with orientation and color, the low fraction of absorbing gas in intermediate azimuthal angles from Kacprzak15, and absorption concentrated near the major and minor axes may be the result of differing ionization conditions throughout the CGM. O VI absorbing gas that is located in the intermediate azimuthal angles may be more susceptible to being ionized out of the O VI phase due to lower densities, resulting in lower equivalent widths (or upper limits on the equivalent width) and lower covering fractions. Conversely, higher gas densities that are due to outflows and inflows along the minor and major axes, respectively, may shield the oxygen from being ionized out of the O VI ionization state and provide more suitable conditions for O VI. If so, higher ionization phases of oxygen may show an orientation dependence in covering fraction and equivalent width, with possibly a higher incidence of gas in the intermediate azimuthal angles when compared to O VI.

5. SUMMARY AND CONCLUSIONS

Using an absorption-selected sample of 29 galaxies (0.13 < z_{gal} < 0.66) from Kacprzak15, we examined the velocity dispersion of O VI absorption as a function of galaxy color, inclination, and azimuthal angle. Each absorber–galaxy pair was identified as part of the “Multiphase Galaxy Halos” survey (e.g., Kacprzak15, Muzahid et al. 2015, 2016) or was obtained from the literature. The galaxies were found within D ~ 200 kpc of a background quasar sightline and have redshifts consistent with detected O VI absorption in HST/COS quasar spectra. Each galaxy is isolated, with no nearby neighbors within 100 kpc and a line-of-sight velocity separation of 500 km s^{-1}. Galaxies were modeled using GIM2D to obtain their inclinations, morphologies, and the azimuthal angle at which the background quasar probes the CGM relative to the projected galaxy major axis. We use the pixel-velocity TPCF method described in MAGiCAT IV and V for Mg II on our O VI absorbers, and compare the results between both Mg II from our previous work and the O VI here. Our findings include the following:

1. In general, the O VI TPCFs are more extended than for Mg II, which is expected if the O VI is collisionally ionized. In orientations in which outflows are expected, such as blue, face-on galaxies probed along the minor axis, the TPCFs are comparable between ions and show similar velocity dispersions.

2. Given the vastly different kinematics of the O VI absorbers compared to Mg II, it is very likely that the two ions trace different components of the CGM. In fact, the seven galaxies that have both detected O VI and Mg II show values of z_{abs} (optical depth-weighted median of absorption) that can be offset by up to 100 km s^{-1}. The O VI absorbers have similar velocity dispersions (chi-squared test result of <1σ) regardless of galaxy color, inclination angle, and azimuthal angle, indicating that the gas is not strongly influenced by the present star formation activity in the host galaxies (i.e., possibly deposited into the CGM by “ancient outflows”). This is despite the findings of Kacprzak15 that O VI is preferentially observed along the projected major and minor axes of galaxies, which are frequently associated with accretion and outflows, respectively.

3. The O VI absorbers have similar velocity dispersions (chi-squared test result of <1σ) regardless of galaxy color, inclination angle, and azimuthal angle, indicating that the gas is not strongly influenced by the present star formation activity in the host galaxies (i.e., possibly deposited into the CGM by “ancient outflows”). This is despite the findings of Kacprzak15 that O VI is preferentially observed along the projected major and minor axes of galaxies, which are frequently associated with accretion and outflows, respectively.

4. The TPCF of the minor axis, edge-on subsample (likely dominated by outflowing material) may be more extended than the major axis, edge-on subsample (4.6σ). This large velocity separation tail is mostly due to a single large equivalent width absorber with a large velocity spread, which is classified as a large-scale galactic outflow by Muzahid et al. (2015). Removing the outlier still results in a marginally significant difference (3.4σ), but this significance is driven more by the major axis, edge-on subsample TPCF being slightly more narrow than the rest of the subsamples. Thus, the significant differences found in Figure 6 are most likely not real.

5. The uniform O VI kinematics with galaxy color and orientation together with the azimuthal angle preference of the O VI absorbers point to ionization effects in the CGM. The gas giving rise to O VI may be uniformly distributed throughout the CGM, but lower densities in intermediate azimuthal angles (30° < Φ < 60°) where outflows and accretion are less likely to occur may result in the oxygen being ionized out of the O VI phase.

To better understand how the kinematics of Mg II and O VI compare, it would be useful to form a large sample of galaxies with both O VI and Mg II absorption detected in high-resolution quasar spectra. As our samples stand now, it is not straightforward to compare the two ion samples to each other because the galaxy property distributions differ for the separate absorbing samples. It is necessary to measure the multiphase kinematics for a set of galaxies like this to understand the multiphase CGM.

Finally, observing the CGM in higher ionization states as a function of galaxy properties is important if the azimuthal angle distribution of O VI is mainly due to differing ionization conditions. The higher ionization states may also show an azimuthal preference, where the incidence rate of higher
ionization absorbers may be larger in the intermediate azimuthal angles than O VI. While it is not currently feasible to study ions such as O VII and O VIII because they are located in the x-ray regime, Ne VIII is observable in the UV. This kinematics–galaxy orientation study could be done with Ne VIII once a large enough sample is obtained.
