Background. Intestinal disorders such as environmental enteric dysfunction (EED) are prevalent in low- and middle-income countries (LMICs) and important contributors to childhood undernutrition and mortality. Autopsies are rarely performed in LMICs but minimally invasive tissue sampling is increasingly deployed as a more feasible and acceptable procedure, although protocols have been devoid of intestinal sampling to date. We sought to determine (1) the feasibility of postmortem intestinal sampling, (2) whether autolysis precludes enteric biopsies’ utility, and (3) histopathologic features among children who died during hospitalization with acute illness or undernutrition.

Methods. Transabdominal needle and endoscopic forces were performed upper and lower intestinal sampling were conducted among children aged 1 week to 59 months who died while hospitalized in Blantyre, Malawi. Autolysis ratings were determined for each hematoxylin and eosin slide, and upper and lower intestinal scoring systems were adapted to assess histopathologic features and their severity.

Results. Endoscopic and transabdominal sampling procedures were attempted in 28 and 14 cases, respectively, with >90% success obtaining targeted tissue. Varying degrees of autolysis were present in all samples and precluded histopathologic scoring of 6% of 122 biopsies. Greater autolysis in duodenal samples was seen with longer postmortem interval (Beta = 0.06, 95% confidence interval, 0.02–0.11). Histopathologic features identified included duodenal Paneth and goblet cell depletion. Acute inflammation was absent but chronic inflammation was prevalent in both upper and lower enteric samples. Severe chronic rectal inflammation was identified in children as young as 5.5 weeks.

Conclusions. Minimally invasive postmortem intestinal sampling is feasible and identifies histopathology that can inform mortality contributors.

Keywords. Minimally invasive tissue sampling; environmental enteric dysfunction; histopathology; child mortality

Undernutrition underlies 45% of child deaths and remains prevalent in low- and middle-income countries, including Malawi, where the under-5 year mortality rate is 42 per 1000 live births: 11% above the global average [1–3]. Causes of undernutrition include food insecurity, recurrent infections, and environmental enteric dysfunction (EED). A largely asymptomatic condition, EED is prevalent in settings with inadequate sanitation and hygiene facilities. It is characterized by intestinal inflammation and villus blunting, malabsorption, permeability facilitating microbe translocation, and systemic inflammation [4, 5]. Accelerating mortality reductions requires improved cause of death (COD) understanding, particularly within populations in which undernutrition and infections are the leading mortality risk factors [3, 6]. Full autopsy is the most comprehensive and accurate method for COD assignment, but is often infeasible because of resource constraints or societal unacceptance [7, 8]. Minimally invasive tissue sampling (MITS) uses transcutaneous needle organ and fluid sampling and is increasingly used as a validated, nondisfiguring, and more acceptable alternative to full autopsy [9, 10]. However, MITS lacks enteric sampling because intestines, largely untethered within the abdominal cavity, likely enable
needles to push away, potentially hindering sampling of this organ. Endoscopy may afford visualization and sampling but has rarely been used, and to our knowledge, never attempted in pediatric postmortem studies [11]. Several potential barriers could preclude this approach, including jaw, pyloric sphincter or anal rigor mortis restricting intubation, and stomach contents or stool interfering with visualization and sampling. Tissue autolysis, driven by microbes and cellular enzymes, may render biopsies uninformative because intestine is the first organ to degrade postmortem [12].

Lack of gastrointestinal interrogation impedes understanding of intestinal infections, EED, and other enteric contributions to childhood deaths. The MITS in Malawi (MiM) study sought to assess postmortem endoscopic intestinal sampling feasibility, determine whether autolysis precludes enteric biopsy utility, and examine enteric histopathologic features among children who died during hospitalization with acute illness or undernutrition.

METHODS

Study Design, Setting, Participant Selection
MiM was conducted at Queen Elizabeth Central Hospital (QECH) in Blantyre, Malawi, a national referral and teaching hospital. MiM started as a substudy at the QECH site of the Childhood Acute Illness & Nutrition (CHAIN) study, which assessed risk factors for mortality among children hospitalized with acute illness or undernutrition in low- and middle-income countries [13]. Because of low enrollment and case fatality among CHAIN-enrolled patients, MiM recruitment expanded to 2 other QECH-based studies and the general pediatric wards. Exclusion criteria were: known terminal illnesses, congenital syndromes, injuries, surgical conditions, and age <1 week or >59 months. Recruitment was August 20, 2018–April 9, 2020.

Study staff approached parents/guardians of eligible children after a respectful period following death. Written informed consent was obtained from parents/guardians. Assistance with coffin purchase, transportation, and grief support was offered to all approached parents/guardians, regardless of consent to participation.

Sampling Procedures
MITS procedures commenced as soon as feasible after obtaining consent. A study gastroenterologist or endoscopist used Olympus GIF-P140, GIF XP-160, or GIF-160 gastroscopes and Olympus FB-231K.A or FB-230.K.A forceps. Gastric and duodenal fluid were aspirated, either prebiopsy (preferred) or postbiopsy after flushing with buffered saline. Biopsies were obtained from stomach, the first (D1), second (D2), and most distal accessible duodenal segments (D3/D4), rectum; and colon last as proximally as possible. Postendoscopy, standard MITS procedures were performed [14].

Transabdominal intestinal needle sampling was initially considered impractical, but was adopted midstudy to assess feasibility. Bard Monopty 16G 100-mm needles were introduced just inferior to the umbilicus and right-side posterolateral for small bowel and ascending colon samples, respectively. All tissues were paraffin embedded, sectioned, and stained with hematoxylin and eosin.

Data Collection
Antemortem clinical data were collected during admission for coenrolled patients and otherwise extracted from medical records. Antemortem clinical test results were abstracted from laboratory reports. Because of incomplete antemortem anthropometric data, postmortem anthropometry was used, as is standard in MITS studies [15, 16]. Two study personnel measured mid-upper arm circumference, weight, and length and where discrepant, measured a third time. The average of 2 closest measurements was used. Z scores were calculated using World Health Organization Anthro software [17]. Severe acute malnutrition (SAM) was defined by mid-upper arm circumference <11.5 cm (among ≥6-month-old children), weight-for-length z score <-3, or nutritional edema [18, 19].

A gastrointestinal pathologist (T-C.L.) rated each intestinal hematoxylin and eosin slide for autolysis, categorized as: (0) no autolysis; (1) <50% of tissue autolyzed; (2) 50%–75%; (3) >75% but <100%; and (4) complete autolysis. All sufficiently intact duodenal slides were scored using the EED Biopsy Consortium histology index, whereby 10 histologic parameters are assigned semiquantitative scores from 0 (normal) to 3 or 4 (severe pathology) [20]. Lower intestinal histology was similarly scored based on 4 ulcerative colitis histological parameters [21]. Because slide preparation quality or autolysis may render certain features unscorable, we calculated total score percent (total score divided by maximum possible among scored parameters) to describe overall histopathologic severity [20].

Data Analysis
Analysis was primarily descriptive because this study was designed to examine the feasibility of adding intestinal sampling to standard MITS procedures and not powered to comprehensively test associations with intestinal autolysis or histopathology. However, once feasibility was determined, we leveraged obtained tissues to explore such associations.

We examined autolysis variability by anatomic location and sampling method (endoscopic vs transabdominal) using paired t tests. Autolysis and histologic score intrindividial variability was determined with intraclass correlation coefficients (ICC) using a 2-way mixed effects model. We used univariate linear regression to explore the effect on autolysis by age, sex, admission diagnosis (sepsis, gastroenteritis), nutritional status (per postmortem anthropometry), human immunodeficiency virus (HIV) status, exposure to antibiotics that are potentially more gut
microbiome disruptive (ceftriaxone, ciprofloxacin) versus less so (amikacin, amoxicillin, fluoxacillin, fluonazole, gentamicin, metronidazole, penicillin, trimethoprim-sulfamethoxazole) [22–24], refrigeration duration, postmortem interval (PMI; time to intestinal sampling), and endoscopically visualized stomach contents (restricted to autolysis of D1 because of proximity). All bodies were refrigerated. Refrigeration time highly correlates with PMI, so refrigeration time was calculated as percentage of PMI. Because the PMI/refrigeration duration and autolysis relationship was of primary a priori interest, they were assessed together in a multivariate model.

We used univariate linear regression to explore influences on histologic severity by age, sex, admission diagnosis (sepsis, gastroenteritis, anemia [can be caused by malabsorption]), HIV status, nutritional status, length of hospital stay, higher dysbiotic potential antibiotics (described previously), and hepatic steatosis (indicator of severe malnutrition).

Data were insufficient to relate blood culture results, blood gas acidosis, antibiotics (any use), and stomach pH to autolysis, and malaria diagnosis and acidosis to histologic severity. Analyses were conducted using Stata/SE 16.1. Significance was defined by 2-tailed alpha = .05. Graphics were generated using RStudio version 1.2.5019.

Ethical Approval
The Malawi National Health Sciences Research Committee (NHSRC 1913) and Oxford University Ethics Committee (OxTREC 34-16) provided ethical approval. The University of Washington Institutional Review Board exempted the study from review (STUDY00003689).

RESULTS
Seventy-five children eligible for this study died on enrollment days. Reasons for not seeking consent included: inability to mobilize a key study member within an appropriate time (n = 8), lack of notification by ward staff (n = 5), or unknown reasons (n = 4). Of 58 caregivers approached, 29 (50%) consented. Reasons for refusal were: lack of perceived benefit (n = 9), preference to immediately take body home (n = 7), cultural/religious concerns (n = 5), poor relationship with healthcare staff (n = 2), consenters unavailable (n = 2), child too young (n = 1), or unknown reasons (n = 3). Table 1 summarizes participant characteristics.

Procedure Feasibility
Upper and lower endoscopic sampling was attempted for all but the final case because of corona virus disease 2019-related circumstances. Upper and lower endoscopy mean (range) duration were 34.4 (20–57) and 10.5 (6–20) minutes, respectively.

At least 1 intestinal biopsy was endoscopically obtained from each of 28 cases, including 21 D1 (75%), 20 D2 (71%), 23 D3/ D4 (82%), 5 colon (18%), and 26 rectum (93%) (Figure 1).

Abbreviations: HIV, human immunodeficiency virus; IQR, interquartile range; SAM, severe acute malnutrition.*Pneumonia (n = 4), bronchiolitis (n = 1), both (n = 2).

Presence of stomach contents (eg, milk) and stool often caused insufficient equipment insufflation by procedure end. This explains colon sampling paucity because colon was the final sampling location, and twice interfered with rectal sampling. One case lacked duodenal sampling because of difficulty negotiating the C-loop. Pyloric sphincter constriction precluded duodenal intubation in 3 cases (PMLs between 2 and 14 hours). Transabdominal needle sampling of small and large intestine was successful in 14 (100%) and 13 (93%) of the last 14 cases, respectively. Across all participants, 26 (90%) and 29 (100%) had at least 1 successful small and large bowel biopsy, respectively, regardless of method.

Tissue Autolysis
All intestinal samples displayed some autolysis (Figure 1, Supplementary Figure 1). Thirty-two biopsies (26%) had <50% autolysis, 59 (49%) had 50%–75%, and 31 (25%) had >75% autolysis. None were completely autolyzed. The mean autolysis rating was 1.9, corresponding to slightly <50%–75% of tissue autolyzed. In contrast, only 1 case demonstrated extraintestinal tissue autolysis, in the brain. Autolysis grading was inconsistent across biopsies within the same individual (ICC = 0.16) (Figure 1), but did not differ by gut location (Table 2). Among cases with both sampling methods, mean autolysis rating was higher in transcutaneous (2.3, standard deviation [SD] = 0.8) than endoscopic biopsies (1.9, SD = 0.7) (P = .040).
Upper intestinal autolysis was 0.4 points (out of 4) higher with a 6-hour increased PMI (95% confidence interval [CI], 0.1–0.7, \( P = .01 \)), without meaningful change after adjusting for refrigeration (as percent of PMI) (Table 3, Supplementary Figure 2). No clear relationship was appreciated between PMI and lower intestinal autolysis.

Rectal autolysis was 0.5 points higher among children diagnosed with sepsis (95% CI, 0.1–0.9, \( P = .032 \)). Endoscopically-obtained small intestine autolysis was 0.6 points lower in those with SAM (95% CI, -1.1 to -0.1, \( P = .014 \)). Antibiotic administration during hospitalization was universal, but those who

|                 | Large intestine (…/13)                        | …                                             | 2.2 (0.6, 1–3)                                | Large intestine (…/11) (…/85)                   | …                                             | 15 (20, 0–50)                                |

*Endoscopic sampling was attempted for cases 1–28. Transabdominal sampling was attempted for cases 16–29. N represents the number of obtained biopsies successfully sampled and examined for autolysis.

*Autolysis ratings were coded as following: (0) no autolysis, (1) <50% of tissue autolyzed, (2) 50%–75%, (3) >75% but some intact tissue, and (4) complete autolysis.

*N represents the number of biopsies that could be examined for histopathologic features (ie, autolysis did not preclude scoring of at least 1 histologic feature).

*Some tissues were unable to be scored because extensive autolysis impeding the identification of histologic features.

*Autolysis rendered some histologic features nonscorable; therefore, total score percent (total score divided by maximum possible score of available criteria) is used to summarize histopathologic findings.
Table 3. Variables Univariately Tested for Association With Intestinal Tissue Autolysis Rating

| Variable                                      | Endoscopically Sampled | Transabdominally Sampled | Combined |

*Bold text indicates statistically significant results (P < .05).
* P < .05.
** P < .01.

aIncludes D1, D2, D3/D4, averaged by participant.

bIncludes endoscopically sampled duodenal tissues (D1, D2, D3/D4) and transabdominally sampled small intestine, averaged by participant.

cIncludes endoscopically sampled rectum and transabdominally sampled large intestine, averaged by participant.

dIncludes ciprofloxacin and ceftriaxone.

eOnly tested for association with D1 because of proximity to gastric contents.
received higher dysbiotic potential antibiotics had 0.5-point lower autolysis than those receiving other antibiotics, although this finding was limited to endoscopically obtained duodenal samples (95% CI, -1.0 to -0.03, \(P = .037\)). Those with endoscopically visible gastric contents had 0.5-point lower autolysis (only assessed in D1) (95% CI, -1.0 to -0.1, \(P = .031\)).

**Intestinal Histopathologic Disease Severity**

Autolysis precluded scoring of 7 (6%) slides. At least 1 slide per case, totaling 115 slides (94%), were scored: 20 D1 (95%), 20 D2 (100%), 22 D3/D4 (96%), 5 colon (100%), and 26 rectal (100%) endoscopic biopsies and 11 transabdominal small (79%) and 11 large intestine samples (85%) (Figure 1, Table 2). Scores were inconsistent across tissues within individuals (ICC = 0.22 for all biopsies, ICC = 0.39 restricted to upper intestine only). Mean scores did not differ by enteric location (Table 2, Supplementary Figure 3). Transabdominally sampled small bowel had lower mean scores than endoscopically obtained (mean total score percent = 6% and 20%, respectively, \(P = .006\)).

Of upper intestinal histology features, Paneth cell depletion was most severely abnormal (mean score = 2 of 3), followed by chronic inflammatory infiltration (mean score = 1.8 of 3) and goblet cell depletion (mean score = 2 of 4) (Table 4, Supplementary Figure 4). Autolysis frequently precluded assessment of foveolar metaplasia, villus architecture, intraepithelial lymphocytes, and epithelial detachment. When assessable, mean scores were low (0, 0.7, 1, 1.3, and 1.5, respectively). Eosinophilic and neutrophilic infiltration were largely assessable, but uncommon (average scores 0.2 and 0, respectively). Lower intestine lacked evidence of neutrophilic infiltration or ulcerations (although the latter was infrequently assessable). Chronic rectal inflammation was prevalent and often severe (mean score = 2 of 3), including among 29% (n = 4) of infants younger than 6 months (Supplementary Figures 5 and 6). We explored factors that might have influenced this trend, but no relationships were identified. We found no relationships between a priori defined characteristics and histology scores.

**DISCUSSION**

To our knowledge, this is the first pediatric use of minimally invasive intestinal sampling. In 22 adults from Hong Kong, Fan et al assessed postmortem laparoscopic and thoracoscopic approaches to various organs and endoscopy of stomach and great vessels. They also visualized (without biopsying) the duodenum endoscopically in 1 patient [25]. Postmortem upper endoscopy was attempted by Denzer et al in 20 German adults [11]. They reached D2 in 17 cases (stomach contents, pyloric atony, and anatomic issues precluded intestinal intubation in the others). However, intestinal sampling was only attempted (successfully) in 1 case. We are unaware of postmortem lower bowel endoscopy reports.
In our study, jaw rigor mortis did not inhibit oral intubation, though occasionally instrumented jaw opening was required. Anal rigor mortis, when present, was easily overcome. Pyloric sphincter rigor mortis impeded duodenal intubation in 3 cases. This phenomenon arises 2 hours postmortem and resolves by 12–14 hours in uncooled bodies [26]. It is encouraging that this obstruction was not more prevalent in this study, where most procedures commenced within 14 hours and all bodies underwent refrigeration. Stomach contents did not preclude endoscopic duodenal sampling. However, food/stool contents frequently blocked insufflation of endoscopy equipment by colon sampling at procedure end. We conclude that if a single endoscope is used per both oral and anal routes, routine colonic sampling is not feasible. Duodenal and rectal sampling is feasible, although needed equipment and clinical expertise may limit implementation to centers with requisite capacity.

The standard MITS procedure uses transcutaneous needle biopsies, but to our knowledge, this method had not been applied intestinally. We included transabdominal small and large bowel sampling for the last 14 cases with near universal success. Rapid needle firing likely facilitated intestinal tissue acquisition. Although likely more scalable than endoscopy, location within the upper intestine cannot be determined by blind biopsy nor can mucosa be grossly visualized. Preliminary data from an ongoing study suggest this approach unreliably yields samples in adults (unpublished). Moreover, preservation tended to be better in endoscopically sampled tissues than transabdominally. Therefore, endoscopic approach may be preferred, except in settings where precluded by resource strain.

Sampling utility is an important consideration even if feasible and scalable. Intestine autolyses early. Microbial colonization is less abundant in the duodenum but likely an important driver of large bowel autolysis [12]. Digestive enzymes may be more involved in the duodenum, particularly D2 where pancreatic secretions drain. Although upper and lower intestine autolysis did not differ in this study, we noted a tendency toward tissue preservation with exposure to higher dysbiotic potential antibiotics (limited to small bowel). Less autolysis in children with SAM might be attributed to microbiome alterations or reduced pancreatic enzymatic activity associated with this condition [27, 28]. Less duodenal autolysis was found in the presence of stomach contents, perhaps because of protection from or competition for enzymatic degradation. Because sepsis was diagnosed by admitting clinician, its relationship with autolysis likely represents a relationship between illness severity at admission and autolysis rather than sepsis specifically.

Greater small bowel autolysis was seen with longer PMI, corroborating prior studies suggesting tissues become histologically uninformative beyond 12–24 hours [29–32]. Our data suggest that sampling is best performed within 6 hours postmortem as no tissues had ≥50% autolysis before this interval (Supplementary Figure 2). However, even samples obtained between 6 and 12 hours often yielded informative histology. Post-12 hours, no tissues had <50% autolysis.

Despite autolysis prevalence, many histologic features were discernible. As expected, epithelial structure was generally undiscernible because luminal surfaces degrade first. However, inflammatory response was scorable in 94% of slides. Duodenal chronic inflammation was prevalent. All tissues were devoid of acute inflammation. This is consistent with findings from biopsies of Zambian and Pakistani children with EED, as was our finding of reduced Paneth and goblet cell density which are important in antimicrobial activity and mucin production, respectively [20]. Depletion may be from rapid cell turnover or impaired stem cell differentiation [33]. EED histopathology investigations have focused on small bowel. Lower intestinal scrutiny has been limited. Rectal histology from this study demonstrated an absence of acute inflammation; however, chronic inflammation was identified in 96% of samples and severe infiltration seen in children as young as 5.5 weeks old. Although Chacko et al’s seminal autopsy investigation lacked inflammation assessment, they demonstrated generally normal fetal and neonatal villus architecture, whereas blunting was noted as early as age 8 weeks and severity increased with age [34]. Although our data are insufficient to explore further, factors including exposure to breastmilk substitutes or contaminated fluids could explain these findings. We hope to explore potential pathogen explanations in future analyses.

Transabdominally obtained small intestine had fewer histologic abnormalities than endoscopically obtained. Histopathology is a presampling phenomenon, so sampling method should not affect this. EED is thought to be a patchy duodenal disorder, as supported by our findings of intraindividual variation, possibly explained by sampling method difference. Because transabdominal sampling is blind, we cannot determine upper intestinal anatomic location and we may be scoring regions less affected than duodenum.

We hoped to explore relationships with histopathology to further elucidate the role of EED and intestinal pathology in child mortality. Though EED is considered an underlying cause of undernutrition, our study was unable to detect such relationship, likely from lack of statistical power [4]. Further, we did not identify relationships between histopathology and demographics, clinical interventions, or admission diagnoses. Pending final COD determination based on all MITS samples could enhance this exploration.

We acknowledge study limitations. Sample size was constrained because MiM was designed to assess feasibility; therefore, our assessment of relationships with autolysis and intestinal histopathology are exploratory. Additionally, participants died while at a referral hospital, where the majority of patients are from lower socioeconomic backgrounds and reside near Blantyre. Results may not generalize to community-based deaths or other populations. Despite these limitations, our study demonstrates that minimally invasive postmortem intestinal sampling is feasible.

and histologically informative. Biopsy ascertainment within 12 hours of death appears to improve tissue preservation. Preservation may also be affected by patient characteristics (e.g., nutritional status, clinical interventions). Histologic interrogation successfully identified and quantified features of EED and rectal chronic inflammation. Future studies with larger sample sizes should elucidate factors affecting autolysis and enteric disease and its role in child mortality and undernutrition.

Supplementary Data
Supplementary materials are available at Clinical Infectious Diseases online. Consisting of data provided by the authors to benefit the reader, the posted materials are not copyedited and are the sole responsibility of the authors, so questions or comments should be addressed to the corresponding author.
