Square Root-based Multi-Source Early PSD Estimation and Recursive RETF Update in Reverberant Environments by Means of the Orthogonal Procrustes Problem

Thomas Dietzen, Simon Doclo, Senior Member, Marc Moonen, Fellow, and Toon van Waterschoot Member

Abstract—Multi-channel short-time Fourier transform (STFT) domain-based processing of reverberant microphone signals commonly relies on power-spectral-density (PSD) estimates of early source images, where early refers to reflections contained within the same STFT frame. State-of-the-art approaches to multi-source early PSD estimation, given an estimate of the associated relative early transfer functions (RETFs), conventionally minimize the approximation error defined with respect to the early correlation matrix, requiring non-negative inequality constraints on the PSDs. Instead, we here propose to factorize the early correlation matrix and minimize the approximation error defined with respect to the early-correlation-matrix square root. The proposed minimization problem – constituting a generalization of the so-called orthogonal Procrustes problem – seeks a unitary matrix and the square roots of the early PSDs up to an arbitrary complex argument, making non-negative inequality constraints redundant. A solution is obtained iteratively, requiring one singular value decomposition (SVD) per iteration. The estimated unitary matrix and early PSD square roots further allow to recursively update the RETF estimate, which is not inherently possible in the conventional approach. An estimate of the said early-correlation-matrix square root itself is obtained by means of the generalized eigenvalue decomposition (GEVD), where we further propose to restore non-stationarities by desmoothing the generalized eigenvalues in order to compensate for inevitable recursive averaging. Simulation results indicate fast convergence of the proposed multi-source early PSD estimation approach in only one iteration if initialized appropriately, and better performance as compared to the conventional approach.

Index Terms—Early PSD estimation, RETF estimation, orthogonal Procrustes problem, unitary constraint, singular value decomposition, generalized eigenvalue decomposition.

I. INTRODUCTION

In many multi-microphone signal processing applications, the recorded microphone signals constitute a mixture of several spatially diverse components, originating from different sources, bearing reverberation and noise. As far as speech is concerned, one typically admits early reflections, while late reverberant components deteriorate the perceived quality and intelligibility [1]. In order to process the various mixture components, many techniques heavily rely on estimates of their power spectral densities (PSDs) [2]–[4].

In recent years, a number of multi-microphone approaches to the estimation of early speech PSDs, late reverberant PSDs, and/or noise PSDs have been proposed, which rely on a spatial correlation matrix model in the short-time Fourier transform (STFT) domain [5]–[15]. In order to estimate these PSDs, some parameters of the correlation matrix model are assumed to be known or estimated beforehand, such as the direction(s) of arrival (DoA(s)) or the relative early transfer function(s) (RETF(s)) associated to the source(s) [5]–[13], or the spatial coherence matrix of the noise or the late reverberant component, where in particular the latter is commonly modeled as a spatially diffuse sound field [6]–[8], [10]–[16]. It should be noted that majority of these approaches consider a single source [5], [8], [10]–[14], while only some consider multiple sources [6], [7], [9], [15], which is the focus of this paper.

In [8], [10], the early speech and late reverberant PSD estimates are obtained by maximum-likelihood estimation, where in [8], both are estimated jointly, and in [10], the late reverberant PSD estimation relies on blocking the early speech component. Given particular coherence matrix estimates, e.g., defined from DoA or RETF estimates (for point sources) or assumptions on the spatial nature of the sound field (for noise and late reverberation), other estimators rely on Frobenius-norm minimization of the approximation error defined with respect to an estimate of the associated correlation matrix component [5]–[8], [9], [11], [12], [15]. Specifically, in [5], the speech PSD is estimated by minimizing the approximation error defined with respect to an estimate of the speech-only correlation matrix component (while reverberation is not considered). In a similar manner, in [8], considering multiple sources, the early PSDs are estimated from an estimate of the early correlation matrix component. In [7], the late reverberant PSD is estimated from an estimate of a blocking-based correlation matrix, generated by blocking the direct components, while the multiple early PSDs are estimated as in [6]. Likewise, one may also jointly estimate several PSDs associated to different kinds of coherence matrices, e.g., one may jointly estimate early speech PSD(s), the late reverberant PSD, and noise PSD(s) [9], [11], [12]. In [15], joint estimation of the RETFs, the early speech PSDs, the late reverberant PSD, and the noise PSDs is proposed using simultaneous confirmatory factor analysis in multiple frames, i.e. by jointly
minimizing a number of approximation errors defined over several frames, during which the RETFs are assumed to be stationary. Note that the PSD estimates based on this type of minimization problem are not inherently guaranteed to be non-negative, requiring either non-negative thresholding, or, alternatively, non-negative inequality constraints. In [14], the estimation of the late reverberant PSD is based on a subspace decomposition, outperforming the late reverberant PSD estimators in [7], [8], [10], while the proposed approach, given an estimate of the early correlation matrix component, some state-of-the-art approaches to early PSD estimation are reviewed in Sec. III, while the proposed approach, given an estimate of the early-correlation-matrix square root, is presented in Sec. IV. In Sec. V we discuss the estimation of the required early correlation-matrix component and its factorization. The proposed approach is evaluated in Sec. VI and followed by a conclusion in Sec. VII.

II. Signal Model

Throughout the paper, we use the following notation: vectors are denoted by lower-case boldface letters, matrices by upper-case boldface letters, \( \mathbf{I} \) and \( \mathbf{0} \) denote identity and zero matrices, \( i \) and \( 1 \) denote the first column of \( \mathbf{I} \) and a vector of ones, respectively, \( \mathbf{A}^T \), \( \mathbf{A}^H \), and \( \mathbf{E}[\mathbf{A}] \) denote the transpose, the complex conjugate transpose or Hermitian, and the expected value of a matrix \( \mathbf{A} \). The operation \( \text{diag}[\mathbf{A}] \) creates a column vector from the diagonal elements of a square matrix \( \mathbf{A} \), \( \text{Diag}[\mathbf{a}] \) and \( \text{Diag}[\mathbf{a}^T] \) create a diagonal matrix with the elements of \( \mathbf{a} \) on its diagonal, \( \text{Diag}[\text{diag}[\mathbf{A}]] \) zeros the off-diagonal elements of \( \mathbf{A} \), and \( \text{tr}[\mathbf{A}] \) denotes the trace of \( \mathbf{A} \). For non-negative \( \mathbf{a} \in \mathbb{R}^N \), \( a^{1/2} \in \mathbb{C}^N \) denotes a complex vector with arbitrary complex argument that satisfies \( \text{Diag}[\mathbf{a}^{1/2}]a^{1/2} = \mathbf{a} \) and hence \( [\mathbf{a}]^{1/2} = \sqrt{\mathbf{a}} \), with absolute value and non-negative square-root applied element-wise. The operation \( \max\{\mathbf{a}_1, \mathbf{a}_2\} \) returns a vector of the element-wise maxima of \( \mathbf{a}_1 \) and \( \mathbf{a}_2 \). \( \|\mathbf{A}\|_F \) denotes the Frobenius norm of \( \mathbf{A} \), whereas \( \|\mathbf{a}\|_2 \) denotes the Euclidian norm of \( \mathbf{a} \). Row \( i \) and column \( j \) of \( \mathbf{A} \) are denoted as \( \mathbf{A}_{i,:} \) and \( \mathbf{A}_{:,j} \), respectively, the element at the intersection as \( \mathbf{A}_{i,j} \), and submatrices spanning rows \( i_1 \) to \( i_2 \) or columns \( j_1 \) to \( j_2 \) as \( \mathbf{A}_{[i_1:i_2, \ldots, j_1:j_2]} \), respectively. \( \mathbb{R}[\mathbf{a}] \) and \( \mathbb{I}[\mathbf{a}] \) denote the real and imaginary part of \( \mathbf{a} \in \mathbb{C} \).

In the STFT domain, with \( l \) and \( k \) indexing the frame and the frequency bin, respectively, let \( x_m(l, k) \) with \( m = 1, \ldots, M \) denote the \( m \)-th microphone signal, with \( M \) the number of microphones. In the following, we treat all frequency bins independently and hence omit the frequency index. We define the stacked microphone signal vector \( \mathbf{x}(l) \in \mathbb{C}^M \),

\[
\mathbf{x}(l) = (x_1(l) \cdots x_M(l))^T
\]

(1)

composed of the reverberant signal components \( \mathbf{x}_n(l) \) with \( n = 1, \ldots, N \) originating from \( N \) point sources, defined equivalently to (1), i.e.

\[
\mathbf{x}(l) = \sum_{n=1}^{N} \mathbf{x}_n(l).
\]

(2)

Each reverberant signal component \( \mathbf{x}_n(l) \) may be decomposed into the early and late reverberant component \( \mathbf{x}_{n|e}(l) \) and \( \mathbf{x}_{n|l}(l) \), i.e.

\[
\mathbf{x}_n(l) = \mathbf{x}_{n|e}(l) + \mathbf{x}_{n|l}(l),
\]

(3)

which are commonly parted by the arrival time of the therein contained reflections and assumed to have distinct spatial properties as outlined below. Early reflections are assumed to arrive within the same frame, with the early components in \( \mathbf{x}_{n|e}(l) \) related by the RETF in \( \mathbf{h}_n(l) \in \mathbb{C}^M \), i.e.

\[
\mathbf{x}_{n|e}(l) = \mathbf{h}_n(l)s_n(l).
\]

(4)

Here, without loss of generality, the RETF \( \mathbf{h}_n(l) \) is assumed to be relative to the first microphone, i.e. \( i^T \mathbf{h}_n(l) = [\mathbf{h}_n(l)]_1 = 1 \), and \( s_n(l) = [\mathbf{x}_{n|e}(l)]_1 \) denotes the early component in the first microphone originating from the \( n \)-th source, in the following referred to as early source image. We define the stacked RETF matrix \( \mathbf{H}(l) \in \mathbb{C}^{M \times N} \), yielding

\[
\mathbf{H}(l) = (\mathbf{h}_1(l) \cdots \mathbf{h}_N(l)),
\]

(5)

\[
i^T \mathbf{H}(l) = [\mathbf{H}(l)]_{1,:} = \mathbf{1}^T.
\]

(6)
Similarly, we stack $s_n(l)$ into $s(l) \in \mathbb{C}^N$, i.e.
\[ s(l) = (s_1(l) \cdots s_N(l))^T, \]
so that the sum of the early components $x_{n|e}(l)$ may be expressed more compactly as
\[ \sum_{n=1}^N x_{n|e}(l) = \mathbf{H}(l)s(l). \]

Further, we assume that $x_{n|e}(l)$ and $x_{n|e}(l)$ are mutually uncorrelated within frame $l$. Let $\Psi_{x}(l) = \mathbb{E}[x(l)x^H(l)] \in \mathbb{C}^{M \times M}$ denote the microphone signal correlation matrix, and let the early and late reverberant correlation matrix $\Psi_{xe}(l)$ and $\Psi_{xe}(l)$ be similarly defined. With Eqs. (3)–(6), we then find
\[ \Psi_{xe}(l) = \Psi_{xe}(l) + \Psi_{xe}(l), \]
wherein $\Psi_{xe}(l)$ generally has rank $N$ and is expressed by
\[ \Psi_{xe}(l) = \mathbf{H}(l)\Phi_{xe}(l)\mathbf{H}^H(l), \]

\[ \Phi_{xe}(l) = \text{Diag}[\phi_{xe}(l)], \]
with $\phi_{xe}(l)$ denoting the PSD of the early source image $s_e(l)$. Note that applying Eqs. (9) to (10)–(11) while using $1^T \Phi_{xe}(l)1 = 1^T \phi_{xe}(l)$, we find that
\[ 1^T \Psi_{xe}(l)1 = (\Psi_{xe}(l))_{1,1} = 1^T \phi_{xe}(l), \]
i.e. the sum of the early PSDs $\phi_{xe}(l)$ equals $[\Psi_{xe}(l)]_{1,1}$. Assuming that $x_{n|e}(l)$ is modeled as diffuse [6]–[8], [10]–[16] with coherence matrix $\Gamma \in \mathbb{C}^{M \times M}$, which may be computed from the microphone array geometry [16] and is therefore considered to be known in the remainder, we may write $\Psi_{xe}(l)$ as
\[ \Psi_{xe}(l) = \phi_{xe}(l)\Gamma, \]
with $\phi_{xe}(l) = \sum_{n=1}^N \phi_{n|e}(l)$,
\[ \phi_{xe}(l) = \sum_{n=1}^N \phi_{n|e}(l), \]
and $\phi_{n|e}(l)$ denoting the PSD of the late reverberant component $x_{n|e}(l)$. The PSDs $\phi_{xe}(l)$ and $\phi_{xe}(l)$ may be highly non-stationary, especially if the point sources are speech sources, while the associated coherence matrices $\mathbf{h}_e(l)\mathbf{h}_e^H(l)$ and $\Gamma$ are commonly assumed to be comparably slowly time-varying or even time-invariant.

Note that with Eqs. (14)–(15), one may easily include further diffuse components, e.g., babble noise, without formally changing the signal model. However, since in this paper, we are mainly concerned with the estimation of the early PSDs $\phi_{xe}(l)$ and the recursive updating of the estimate of the RETFs $\mathbf{H}(l)$, we restrict the discussion and simulations, cf. Sec. VII, to the example of late reverberation for the sake of conciseness.

Further, note that while the above signal model is commonly and effectively used [6]–[8], [10]–[15] due to its simplicity, it may be said to be deficient in a number of aspects. The assumption that $x_{n|e}(l)$ and $x_{n|e}(l)$ are mutually uncorrelated within frame $l$ may be violated due to overlapping windows in the STFT-processing or source signals remaining correlated over several frames. The assumption that $\Psi_{xe}(l)$ in (10) has rank $N$ implicitly relies on the assumption that the frequency bins may be treated independently, ignoring cross-bin dependencies [26]. Finally, related to that, there may be components that may be modeled neither by the rank-$N$ component $\Psi_{xe}(l)$ in (10) nor by the diffuse component $\Psi_{xe}(l)$ in (14), depending on the geometry and physical properties of the acoustic environment.

In the remainder, as we mostly consider the single frame $l$ only, we also drop the frame index for conciseness and refer back to it only where necessary, namely when we differentiate the frames $l$ and $l-1$ in recursive equations.

III. Early PSD Estimation based on the Early Correlation Matrix

In this section, we discuss some state-of-the-art approaches to the estimation of the early PSDs $\phi_{xe}$ based on the signal model in (10)–(13). In the following, we refer to (10)–(13) as the conventional signal model. We develop our discussion from the premise that estimates $\hat{\Psi}_{xe}$ and $\hat{\mathbf{H}}$ of the early correlation matrix $\Psi_{xe}$ and the RETFs $\mathbf{H}$ in (10) are readily available. Throughout the paper, despite being irrelevant to the approaches discussed in this section, we consider $\hat{\Psi}_{xe}$ to generally have rank $N$, similar to $\Psi_{xe}$. A rank-$N$ estimator of $\Psi_{xe}$ is described in Sec. VII. Further, we assume that $\hat{\mathbf{H}}$ satisfies $\hat{\mathbf{H}}^H = 1^T$, cf. $\mathbf{H}$ in (6).

Given the estimates of a early correlation matrix $\hat{\Psi}_{xe}$ and the therein superimposed coherence matrices $\hat{\mathbf{h}}_e, \hat{\mathbf{h}}_e^H$, one may estimate the associated PSDs $\hat{\phi}_{xe}, \hat{\phi}_{xe}$, as described in [4], [9], [11], [12]. Adopting this approach, we define the approximation error as a function of $\phi_{xe}$ as
\[ E_c(\phi_{xe}) = \hat{\Psi}_{xe} - \hat{\mathbf{H}}\text{Diag}[\phi_{xe}]\hat{\mathbf{H}}^H, \]
where the subscript $c$ stands for conventional. The early PSDs $\phi_{xe}$ can then be estimated by Frobenius-norm minimization of the approximation error followed by non-negative thresholding, i.e.
\[ \phi_{xe}^* = \arg\min_{\phi_{xe}} \| E_c(\phi_{xe}) \|^2_F, \]
\[ \phi_{xe} = \max(\phi_{xe}^*, 0). \]

The non-negative thresholding in (18) is necessary as the elements of $\phi_{xe}^*$ in (17) may in fact be negative, conflicting with the notion of $\phi_{xe}$ being a vector of PSDs. If $\mathbf{H}^H \mathbf{H}$ has full rank, which (without sufficiency) requires $N \leq M$, the problem in (17) has a unique solution given by
\[ \phi_{xe}^* = \mathbf{A}_c^{-1} \mathbf{b}_c, \]
where $\mathbf{A}_c \in \mathbb{R}^{N \times N}$ and $\mathbf{b}_c \in \mathbb{R}^N$ are defined by
\[ [\mathbf{A}_c]_{n,n'} = (\hat{\mathbf{h}}_e^H \hat{\mathbf{h}}_n)^2, \]
\[ \mathbf{b}_c = \text{diag}(\mathbf{H}^H \hat{\Psi}_{xe} \mathbf{H}). \]

Alternatively, instead of simple thresholding after solving (17), one may solve the minimization problem subject to the non-negative inequality constraint $\phi_{xe} \geq 0$, as proposed in [15].

1In [6], as in our case, point-source coherence matrices of rank one are considered, while in [9], [11], [12], without rendering a difference in the principle approach, general coherence matrices are considered.
In addition to this, one may further impose a soft constraint on $1^T \Phi s$, corresponding to (13), i.e. one may define a soft-constraint error as a function of $\Phi s$, to be penalized as

$$ e_c(\Phi s) = [\Psi_{s,11}]_1 - 1^T \Phi s = [E_c(\Phi s)]_1.1. $$

(22)

The resulting minimization problem can then be written as

$$ \hat{\Phi} = \arg \min_{\Phi} \left| E_c(\Phi s) \right|_F^2 + \alpha |e_c(\Phi s)|^2 $$

s.t. $\Phi \geq 0$, 

(23)

where $\alpha$ is the penalty factor. For $\alpha \to \infty$, a hard constraint $1^T \Phi s = [\Psi_{s,11}]_1$, which is introduced, may however not be desirable due to potential estimation errors in $[\Psi_{s,11}]_1$. Note that in (13), instead of a soft constraint, a box constraint on $1^T \Phi s$ has been used. For the sake of comparison to the algorithm proposed in Sec. IV, however, we restrict our discussion to the soft constraint. Due to the inequality constraint $\Phi s \geq 0$, the problem in (23) does not have a closed-form solution and may require several iterations in order to be solved. Using the proximal gradient method [27], [28], we may solve (23) by iterating the below set of equations until convergence is reached,

$$ \Phi'^{(i)} s = \Phi^{(i-1)} s - \mu (b_c - A c \Phi^{(i-1)} s), $$

(24)

$$ \hat{\Phi} ^{(i)} s = \max (\Phi'^{(i)} s), 0, $$

(25)

where $i$ is the iteration index, $\mu$ the step-size, and $b_c - A c \Phi^{(i-1)} s$ the gradient with $A c \in \mathbb{R}^{N \times N}$ and $b c \in \mathbb{R}^N$ defined by

$$ A c = A c_0 + \alpha I 1^T, $$

(26)

$$ b c = b c_0 + \alpha [\Psi_{s,11}]_1 1, $$

(27)

and $A c_0$ and $b c_0$ defined in (20)–(21). As initial value, it is straight-forward to choose $\Phi s^{(0)} = A c_0 b c$, which yields the global minimum if $\Phi s^{(0)} \geq 0$. In this case therefore, convergence is reached after one iteration of (24)–(25). In any case, for $\Phi s^{(0)} = A c_0 b c$, and $\alpha = 0$, the estimate obtained after one iteration of (24)–(25) corresponds to the estimate defined by (17)–(19). We therefore use (25) as a reference for comparison in the remainder. In the following, we refer to (23) as the conventional minimization problem (conventional MP).

IV. EARLY PSD ESTIMATION AND RECURSIVE RETF UPDATE BASED ON THE EARLY-CORRELATION-MATRIX FACTORIZATION

In this section, in order to estimate the early PSDs $\Phi s$, instead of defining the approximation error to be minimized with respect to $\Psi_{s,11}$ as in (16), we propose to define the approximation error with respect to the square root $\Psi_{s,11}^{1/2} \in \mathbb{C}^{M \times N}$ of $\Psi_{s,11}$, satisfying $\Psi_{s,11}^{1/2} \Psi_{s,11}^{1/2} = \Psi_{s,11}$. As to be shown, instead of directly estimating the diagonal of $\Phi s = \text{Diag}[\Phi s]$, the resulting minimization problem now consists in estimating a unitary matrix $\Omega \in \mathbb{C}^{N \times N}$ and the diagonal of $\Phi s^{1/2} = \text{Diag}[\Phi s^{1/2}]$, which constitutes a generalization [21] of the so-called orthogonal Procrustes problem [22], [23]. Since the early PSDs herein are represented by $\Phi s = \text{Diag}[\Phi s^{1/2}]$, the corresponding estimate $\Phi s$ is guaranteed to be non-negative, such that a non-negative inequality constraint as in (23) is not required. Further, we show that the obtained estimates $\Omega$ and $\Phi s^{1/2}$ may be used to recursively update the RETF estimate $\tilde{H}$, which is not inherently possible from the estimate $\Phi s$ given by (23).

In Sec. IV-A as a pre-requisite to our derivation, we discuss the factorization of the conventional signal model in (10)–(13), yielding the square-root signal model. In Sec. IV-B, based upon the square-root signal model and given the estimates $\Psi_{s,11}^{1/2}$ and $\tilde{H}$, we then define and solve the square-root minimization problem (square-root MP). In Sec. IV-C we discuss the recursive updating of the the RETF estimate $\tilde{H}$.

A. Early-Correlation-Matrix Factorization

We consider the factorization of the rank-$N$ matrices on both sides of (10). On the left-hand side of (10), we define the square root $\Psi_{s,11}^{1/2} \in \mathbb{C}^{M \times N}$ such that $\Psi_{s,11}^{1/2} \Psi_{s,11}^{1/2} = \Psi_{s,11}$. Note that the product is invariant to right-multiplication of a particular square root with any unitary matrix, and so $\Psi_{s,11}^{1/2}$ is not unique. On the right-hand side of (10), with $\Phi s^{1/2} = \text{Diag}[\Phi s^{1/2}]$ and $\text{Diag}[\Phi s^{1/2}] \Phi s^{1/2} = \Phi s$, we define the square root $H \Phi s^{1/2}$ such that $H \Phi s^{1/2} H^H = H \Phi s H^H$. Note that while the magnitude of the elements in $\Phi s^{1/2} \in \mathbb{C}^{N \times N}$ is well-defined, namely by $|\Phi s^{1/2}| = \sqrt{\Phi s}$, their complex argument may be chosen arbitrarily, and so $\Phi s^{1/2}$ is not unique. The non-uniqueness of both square roots implies that while their respective products on both sides of (10) coincide, the said square roots themselves generally do not, i.e. we have $\Psi_{s,11}^{1/2} \neq H \Phi s^{1/2}$. Hence, for a particular $\Psi_{s,11}^{1/2}$ and $\Phi s^{1/2}$, we introduce the unitary matrix $\Omega \in \mathbb{C}^{N \times N}$, which is such that $\Psi_{s,11}^{1/2} \Omega$ and $H \Phi s^{1/2}$ do coincide, i.e. we may summarize

$$ \Psi_{s,11}^{1/2} \Omega = H \Phi s^{1/2}, $$

(28)

$$ \Phi s^{1/2} = \text{Diag}[\Phi s^{1/2}], $$

(29)

$$ \Omega \Omega^H = I, $$

(30)

where right-multiplying each side of (28) with its Hermitian yields (10). At this point, in order to stress the meaning of (28)–(30), we add that the column vectors $[\Psi_{s,11}^{1/2}]_n$ and $[H \Phi s^{1/2}]_n = h_n \varphi s^{1/2}$ form generally different bases of the same vector space, and hence $\Omega$ implements a change of basis.

Applying (6) to (28)–(29) and noting that $1^T \text{Diag}[\Phi s^{1/2}] = \varphi s^{1/2}$, we find that $\varphi s^{1/2}$ and $\Omega$ satisfy

$$ 1^T \Psi_{s,11}^{1/2} \varphi s^{1/2} = [\Psi_{s,11}^{1/2} \Omega]_1 = \varphi s^{1/2} $$

(31)

where right-multiplying each side of (31) with its Hermitian yields (13). We further note that if $\Omega$ was known for a given square root $\Psi_{s,11}^{1/2}$, then $\Phi s^{1/2}$ could be obtained from (31) immediately. In the following, we refer to (28)–(31) as the square-root signal model.

A particular case is obtained for $N=1$, where $\Omega$ and $\Phi s^{1/2}$ are scalar, while $H = h$ and $\Phi s^{1/2} = \varphi s^{1/2}$ are proportional column vectors. In this case, given an estimate $\hat{\psi s}^{1/2}$, we may even estimate $h$ by $\hat{h} = \hat{\psi s}^{1/2} / |\hat{\psi s}^{1/2}|$, satisfying $|h|_1 = 1$, cf. [8]. In essence, despite somewhat different derivation and terminology, this is equivalent to the approach taken in subspace-based single-source RETF estimation [18].
B. Orthogonal Procrustes-based Early PSD Estimate

In this section, based on the square-root signal model in (28)–(31), we seek unitary and diagonal estimates \( \hat{\Omega} \) and \( \text{Diag}[\hat{\phi}_s^{1/2}] \) of \( \Omega \) and \( \text{Diag}[\phi_s^{1/2}] \). Similarly to Sec. III, we develop our discussion from the premise that estimates \( \hat{\phi}_s^{1/2} \) and \( \hat{H} \) of the early-correlation-matrix square root \( \Psi_s^{1/2} \) and the RETF \( H \) in (23) are readily available, with \( \hat{\Psi}_s^{1/2} \) generally of rank \( N \) and \( \hat{H} = \hat{\Omega}^{1/2} \). An estimator of \( \hat{\Psi}_s^{1/2} \) is described in Sec. IV-B while Sec. IV-C describes a recursive update scheme for \( \hat{H} \).

Similarly to Sec. III, now based on the square-root signal model in (28)–(30) instead of the conventional signal model in (10), we define the approximation error as a function of \( \Omega \) and \( \phi_s^{1/2} \), i.e.

\[
E_{sq}(\Omega, \phi_s^{1/2}) = \hat{\Psi}_s^{1/2} \Omega - \hat{H} \text{Diag}[\phi_s^{1/2}],
\]

which is akin to \( E_c(\phi_s) \) in (16), and where the subscript \( sq \) stands for square root. Further, now based on the square-root signal model in (31) instead of the conventional signal model in (13), we define a soft-constraint error as a function of \( \Omega \) and \( \phi_s^{1/2} \) to be penalized as

\[
e_{sq}(\Omega, \phi_s^{1/2}) = \| \hat{\Psi}_s^{1/2} \Omega \|_F^2 - \| \phi_s^{1/2} \|^2_2 = \| E_{sq}(\Omega, \phi_s^{1/2}) \|_F^2,
\]

which is akin to \( e_c(\phi_s) \) in (22). Note that while \( e_c(\phi_s) \) defines an error on the sum of the early PSDs, \( e_{sq}(\Omega, \phi_s^{1/2}) \) instead defines an error on each of the early square PSD roots and is therefore more informative. Based on (32), (33), and the unitary constraint in (30), we define the minimization problem,

\[
\begin{align*}
\{ \hat{\Omega}, \phi_s^{1/2} \} = & \arg \min_{\Omega, \phi_s^{1/2}} \| E_{sq}(\Omega, \phi_s^{1/2}) \|_F^2 + \alpha \| e_{sq}(\Omega, \phi_s^{1/2}) \|_2^2 \\
\text{s.t.} & \quad \Omega^{H} = \mathbf{I},
\end{align*}
\]

(34)

which is akin to the conventional MP in (23) and referred to as the square-root minimization problem (square-root MP) in the following. While the unitary constraint in (33) does not have an equivalent in (23), the inequality constraint \( \phi_s \geq 0 \) used in (23) is not required in (34), as in the square-root signal model, we find that \( \phi_s = \text{Diag}[\phi_s^{1/2}] \phi_s^{1/2} \), and therefore the corresponding estimate \( \hat{\phi}_s \) is guaranteed to be non-negative.

Problems of the kind as in (34), i.e. Frobenius-norm minimization problems seeking a unitary and a diagonal matrix, here \( \Omega \) and \( \text{Diag}[\phi_s^{1/2}] \), constitute a generalization [21] of the so-called orthogonal Procrustes problem [21, 23], which seeks a unitary matrix only. As outlined in the following, under a specific rank condition, the orthogonal Procrustes problem has a unique closed-form solution, which is found by means of the SVD [22, 23]. The generalized orthogonal Procrustes problem, on the contrary, does not have a unique closed-form solution, but may be solved iteratively [21]. In particular, along the lines of [21], we propose to solve (34) by alternatingly (re-)estimating \( \hat{\Omega} \) and \( \phi_s^{1/2} \) until convergence is reached, namely by solving the orthogonal Procrustes problem and the soft-constrained convex problem, respectively,

\[
\hat{\Omega}^{(i)} = \arg \min_{\Omega} \| E_{sq}(\Omega, \phi_s^{1/2}\{(i-1)\}) \|_F^2
\]

s.t. \( \Omega^{H} = \mathbf{I}, \)

\[
\phi_s^{1/2\{(i)\}} = \arg \min_{\phi_s^{1/2}} \| E_{sq}(\hat{\Omega}^{(i)}, \phi_s^{1/2}) \|_F^2 + \alpha \| e_{sq}(\hat{\Omega}^{(i)}, \phi_s^{1/2}) \|_2^2,
\]

(36)

where the soft constraint is applied in (36) only, i.e. once per iteration. Using (32), by expansion of the Frobenius norm in (35), it is easily shown [22, 23] that (35) is equivalent to

\[
\hat{\Omega}^{(i)} = \arg \max_{\Omega} \Re \{ \Omega \Omega^{H} \text{Diag}[\phi_s^{1/2\{(i-1)\}}] \}
\]

s.t. \( \Omega^{H} = \mathbf{I}, \)

\[
\text{C}^{(i-1)} = \text{Diag}[\hat{\phi}_s^{1/2\{(i-1)\}}] \hat{H}^{H} \hat{\phi}_s^{1/2\{(i)\}}
\]

(37)

If \( \text{C}^{(i-1)} \) has full rank, which (without sufficiency) requires \( N \leq M \), the problem in (35) has a unique closed-form solution, which is based on the SVD of \( \text{C}^{(i-1)} \). Precisely, if we decompose \( \text{C}^{(i-1)} \) as

\[
\text{C}^{(i-1)} = U_{\Sigma} U_{\Sigma}^{H},
\]

(39)

where \( \Sigma \in \mathbb{R}^{N \times N} \) is a diagonal matrix of singular values and both \( U_{\Sigma} \in \mathbb{C}^{N \times N} \) and \( U_{\Sigma} \in \mathbb{C}^{N \times N} \) are unitary, then \( \hat{\Omega}^{(i)} \) is given by

\[
\hat{\Omega}^{(i)} = U_{\Sigma} U_{\Sigma}^{H},
\]

(40)

With (32) and (33), the solution to (36) is easily found as

\[
\hat{\phi}_s^{1/2\{(i)\}} = A_{sq}^{-1} b_{sq}^{(i)},
\]

(41)

with \( A_{sq} \in \mathbb{R}^{N \times N} \) and \( b_{sq}^{(i)} \in \mathbb{C}^{N} \) are defined by

\[
A_{sq} = \text{Diag}[\hat{H}^{H} \hat{H} + \alpha \mathbf{I}],
\]

\[
b_{sq}^{(i)} = \text{diag}[\hat{H}^{H}(I + \alpha \mathbf{i} \Omega) \hat{\phi}_s^{1/2\{(i)\}}] = \text{diag}[\hat{H}^{H} \hat{\phi}_s^{1/2\{(i)\}} \hat{\phi}_s^{1/2\{(i)\}}] = \text{diag}[\hat{H}^{H} \hat{\phi}_s^{1/2\{(i)\}}] + \alpha \| \hat{\phi}_s^{1/2\{(i)\}} \|_F^2.
\]

(43)

The set of equations (42–43) is akin to (26–27) for the conventional MP. Note that for \( \alpha \to \infty \), the soft constraint in the square-root MP in (36) becomes a hard constraint and, moreover, solely determines \( \hat{\phi}_s^{1/2\{(i)\}} \) as \( \hat{\phi}_s^{1/2\{(i)\}} = \text{Diag}[\Psi_s^{1/2\{(i)\}}] \), according to (41). This is not the case for the soft constraint in the conventional MP in (23).

Note that since the problem in (34) is non-convex, the iteration in (35)–(36) is guaranteed not to converge to a global minimum [21]. The initial value \( \hat{\phi}_s^{1/2\{(0)\}} \) of the iteration may, e.g. be chosen based on the sum constraint in (13) as \( \hat{\phi}_s^{1/2\{(0)\}} = \sqrt{\left[ \hat{\Psi}_s^{1/2\{(0)\}} \right]_{1,1}/N} \), or based on the comparably lowly complex estimator in (17)–(18), here denoted by \( \hat{\phi}_s^{1/2\{(0)\}} \), as \( \hat{\phi}_s^{1/2\{(0)\}} = \sqrt{\bar{\phi}_s^{1/2\{(0)\}} / \Omega} \). Here, the latter provides faster convergence, cf. Sec. VI-A.

C. Recursive RETF Update

Based on the square-root model in (28), the estimates \( \hat{\Omega} \) and \( \hat{\phi}_s^{1/2\{(0)\}} \) obtained as discussed in Sec. IV-B may also be used to recursively update the RETF estimate \( \hat{H} \). In the following, we differentiate the prior and posterior estimates \( \hat{H} \) and \( \hat{H}^{\text{H}} \), and propose to simply propagate the posterior in the previous frame to the prior in the current frame, i.e.

\[
\hat{H}(l) = \hat{H}^{\text{H}}(l-1).
\]

(44)
In each frame, we use $\hat{H}$ to obtain $\Omega$ and $\hat{\varphi}_{s}^{1/2}$ with \(45\) and \(46\), and then use $\hat{H}$ and $\hat{\varphi}_{s}^{1/2}$ to obtain $\hat{H}^{+}$, where we again resort to the square-root signal model in \(29\). To this end, we define the approximation error as a function of $H$,

$$E_{sq}(H) = \Psi_{x_{s}}^{1/2} \Omega - H \text{ Diag}[\hat{\varphi}_{s}^{1/2}]$$

which is similar to \(32\). Based upon \(45\) and the constraint in \(6\), we define the minimization problem,

$$\hat{H}^{+} = \arg\min_{H} \|E_{sq}(H)\|_F^2 + \|(H - H) \text{ Diag}[\sqrt{\beta}]\|_F^2$$

\(s.t.\ i^{T}H = 1^{T}\) \(46\),

where the penalty term $\|\hat{H} - H\|_F^2$ is the Levenberg-Marquardt regularization \(29, 30\) in that it penalizes deviation from the previous (i.e., the prior) estimate $H$. Here, we leave $\beta$ subject to tuning, as outlined below.

In this respect, recall that according to \(28\), both $\hat{\Psi}_{x_{s}}^{1/2}$ and $\hat{H}$ span the same column space. However, due to modeling and estimation errors, this is not necessarily true for the corresponding estimates $\hat{\Psi}_{x_{s}}^{1/2}$ and $\hat{H}$. In particular, if the $n$th source image has a comparably low early PSD $\varphi_{s}$, or is inactive, then the associated subspace dimension will not be well or not at all be represented in $\hat{\Psi}_{x_{s}}^{1/2}$, and both $\hat{\Omega}_{s_{i}}$ and $\hat{\varphi}_{s}$ may exhibit comparably large estimation errors. Further, the estimate $\varphi_{s}^{1/2}$ may contain residual late reverberation due to erroneous separation of $\hat{\Psi}_{x}$ into $\hat{\Psi}_{x_{s}}$ and $\hat{\Psi}_{x_{t}}$, cf. \(7\), Sec. \(V\) in Sec. \(VI\) in such a case, one would preferably rely on the prior estimate $\hat{h}_{n}$ instead of updating based on $\hat{\Omega}_{s_{i}}$ and $\varphi_{s}^{1/2}$. Considering the solution to \(46\), which is given by

$$\begin{align*}
\hat{H}^{+}_{1,:} &= 1^{T}, \\
\hat{H}^{+}_{2:M,:} &= \left[ (\hat{\Psi}_{x_{s}}^{1/2} \text{ Diag}[\hat{\varphi}_{s}^{1/2}] + \hat{H} \text{ Diag}[\beta]) \cdot \text{Diag}^{-1}[\hat{\varphi}_{s} + \beta] \right]_{2:M,:}
\end{align*}$$

\(48\)

we indeed find that the smaller $\hat{\varphi}_{s}$ as compared to $\beta_{n} = [\beta]_{n}$, the more $\hat{h}_{n}$ relies on $\hat{h}_{n}$, as desired. In order to further increase robustness against modeling and estimation errors, source inactivity and residual late reverberation in $\hat{\varphi}_{s}$, we propose to make $\beta_{n}$ time-varying with binary values. More precisely, we base $\beta_{n}$ on the ratio

$$\xi = \hat{\varphi}_{s}/(1^{T} \hat{\varphi}_{s} + \varphi_{reg}),$$

where $\xi_{n} = [\xi]_{n} \in [0, 1]$. Here, $\varphi_{reg}$ may be used for regularization, e.g., we may choose $\varphi_{reg} = \varphi_{x_{d}}$ in order to limit $\xi_{n}$ in frames where pre-dominantly late reverberation is estimated. Given $\xi_{n}$, we set $\beta_{n}$ as

$$\beta_{n} = \begin{cases} \\
\beta & \text{if } \xi_{n} \geq \xi_{th} \\
\rightarrow \infty & \text{else}
\end{cases}$$

\(50\)

and thereby resort to $\hat{h}_{n}^{+} = \hat{h}_{n}$ if $\xi_{n}$ is smaller than the pre-defined threshold $\xi_{th}$. The value $\beta$, used if $\xi_{n} \geq \xi_{th}$, should scale in relation to the dynamic range of $\hat{\varphi}_{s}$, and may be chosen depending on the (estimated) probability density function of the complex STFT coefficients $s_{n}$, cf. Sec. \(VI\).

Note that in order to start the recursion defined by \(44\), \(35\)-\(36\), and \(46\), an initial estimate $H(0)$ is required, which may be based on, e.g., initial single-source RETF estimates acquired from segments with mutual-exclusively active sources \(18\), or some initial knowledge or estimates of the associated DoAs \(6\), \(19\), \(20\).

V. Subspace-based Early Correlation Matrix Estimation

In Sec. \(III\) and Sec. \(IV\) we respectively assumed that the early-correlation-matrix estimate $\hat{\Psi}_{x_{s}}$ and its square root $\hat{\Psi}_{x_{s}}^{1/2}$ of rank $N$ are available. In this section, we discuss how to obtain these estimates from the microphone signals $x$. We estimate $\hat{\Psi}_{x} = E[xx^{T}]$ by recursively averaging $xx^{T}$, yielding the smooth estimate $\hat{\Psi}_{x}[\mathcal{N}]$, and its equally smooth subspace representation based on the GEVD. From the latter, we first define a desmoothed estimate $\hat{\Psi}_{x}$, and second extract the early component $\hat{\Psi}_{x_{e}}$ and its square root $\hat{\Psi}_{x_{e}}^{1/2}$.

In Sec. \(V-A\) we introduce the subspace model of $\hat{\Psi}_{x}$. In Sec. \(V-B\) we obtain the smooth and desmoothed estimates $\hat{\Psi}_{x}[\mathcal{N}]$ and $\hat{\Psi}_{x_{e}}$ respectively. In Sec. \(V-C\) given $\hat{\Psi}_{x}$, we then retrieve a subspace-based rank-$N$ estimates $\hat{\Psi}_{x_{s}}$ and $\hat{\Psi}_{x_{t}}^{1/2}$.

A. Correlation Matrix Subspace Decomposition

In each frame $l$, we define the GEVD \(31\) of $\hat{\Psi}_{x}$ and the diffuse coherence matrix $\Gamma$, cf. \(14\), i.e.

$$\hat{\Psi}_{x} = \Gamma \Lambda_{x}, \quad (51)$$

with $\Lambda_{x} = \text{Diag}[\lambda_{x}]$, \(52\) where $\lambda_{x} \in \mathbb{R}^{M}$ comprises the generalized eigenvalues, and the columns of $P \in \mathbb{C}^{M \times M}$ comprise the associated generalized eigenvectors. In the GEVD, the generalized eigenvectors in $P$ are uniquely defined up to a scaling factor, and for any factorization $\Gamma = \Gamma_{1}^{1/2} \Gamma_{2}^{1/2}$, we find that $\Gamma_{2}^{1/2}P$ is column-wise orthogonal due to $\hat{\Psi}_{x}[\mathcal{N}]$ being Hermitian. In the following, without loss of generality, we assume the eigenvectors to be scaled such that $\Gamma_{2}^{1/2}P$ is unitary, i.e.

$$P^{H}\Gamma P = I, \quad (53)$$

and therefore, combining \(51\) and \(53\),

$$P^{H}\hat{\Psi}_{x} = \Lambda_{x}, \quad (54)$$

An alternative, but mathematically equivalent formulation to the GEVD in \(51\) is given by the EVD of the pre-whitened matrix $\hat{\Psi}_{x}^{\prime} = \Gamma_{1}^{1/2} \hat{\Psi}_{x} \Gamma_{2}^{-1/2}$, \(14\), \(18\), \(32\), which is defined by $\hat{\Psi}_{x}^{\prime}P^{\prime} = P^{\prime}\Lambda_{x}^{\prime}$. By comparison with \(51\), we find $\Lambda_{x}^{\prime} = \lambda_{x}$ and $P^{\prime} = \Gamma_{2}^{1/2}P$, provided that the respective (generalized) eigenvalues are sorted in the same order, and the (generalized) eigenvectors scaled accordingly.

For convenience of presentation, assume that the generalized eigenvalues in $\lambda_{x}$ are sorted in a descending order, and the generalized eigenvectors in $P$ are sorted accordingly. Then, inserting $\hat{\Psi}_{x} = \hat{\Psi}_{x_{s}} + \hat{\Psi}_{x_{t}}$, with $\hat{\Psi}_{x_{s}} = \varphi_{x_{s}} \Gamma$, cf. \(9\) and \(14\), into \(54\) while making use of \(53\) yields

$$\Lambda_{x} = P^{H}\hat{\Psi}_{x_{s}}P + \varphi_{x_{s}}I, \quad (55)$$

An alternative, but mathematically equivalent formulation to the GEVD in \(51\) is given by the EVD of the pre-whitened matrix $\hat{\Psi}_{x}^{\prime} = \Gamma_{1}^{1/2} \hat{\Psi}_{x} \Gamma_{2}^{-1/2}$, \(14\), \(18\), \(32\), which is defined by $\hat{\Psi}_{x}^{\prime}P^{\prime} = P^{\prime}\Lambda_{x}^{\prime}$. By comparison with \(51\), we find $\Lambda_{x}^{\prime} = \lambda_{x}$ and $P^{\prime} = \Gamma_{2}^{1/2}P$, provided that the respective (generalized) eigenvalues are sorted in the same order, and the (generalized) eigenvectors scaled accordingly.

For convenience of presentation, assume that the generalized eigenvalues in $\lambda_{x}$ are sorted in a descending order, and the generalized eigenvectors in $P$ are sorted accordingly. Then, inserting $\hat{\Psi}_{x} = \hat{\Psi}_{x_{s}} + \hat{\Psi}_{x_{t}}$, with $\hat{\Psi}_{x_{s}} = \varphi_{x_{s}} \Gamma$, cf. \(9\) and \(14\), into \(54\) while making use of \(53\) yields

$$\Lambda_{x} = P^{H}\hat{\Psi}_{x_{s}}P + \varphi_{x_{s}}I, \quad (55)$$
wherein $\Psi_x$ and in consequence $P''\Psi_x P$ generally have rank $N$, and the latter in addition is diagonal, i.e. if $N < M$ we have

$$P''\Psi_x P = \begin{pmatrix} \Lambda_x & 0 \\ 0 & 0 \end{pmatrix},$$

(56)

with $\Lambda_x = \text{Diag}[\lambda_x]$, (57)

and $\lambda_x \in \mathbb{R}^N$.

### B. Recursive Correlation Matrix Estimation and Desmoothing

We compute a smooth estimate $\hat{\Psi}_x|_{\text{sm}}$ of $\Psi_x$ by recursively averaging $xx^H$ using some pre-defined forgetting factor $\zeta \in (0, 1)$, i.e.

$$\hat{\Psi}_x|_{\text{sm}}(l) = \zeta\hat{\Psi}_x|_{\text{sm}}(l-1) + (1-\zeta)x(l)x^H(l),$$

(58)

and perform the GEVD $\hat{\Psi}_x|_{\text{sm}} P = \hat{P}\hat{\Lambda}_x|_{\text{sm}}$ similar to (51)–(54), with $\hat{P}$ an estimate of $P$ and $\hat{\Lambda}_x|_{\text{sm}} = \text{Diag}[\hat{\lambda}_x|_{\text{sm}}]$ a smooth estimate of $\lambda_x$. Note that in order to excite all subspace dimensions and the associated generalized eigenvalues and hence to achieve a meaningful decomposition, $\hat{\Psi}_x|_{\text{sm}}$ needs to be well-conditioned, and so $\zeta$ must be sufficiently close to one. As discussed in Sec. II the PSDs $\varphi_{x_{\ell}}$ and $\varphi_{x_x}$ may be highly non-stationary, while the associated coherence matrices $\mathbf{H}_n, H_n^H$ and $\mathbf{T}$ are commonly assumed to be comparably slowly time-varying or even time-invariant. In theory, a linear combination of the PSDs $\varphi_{x_{\ell}}$ and $\varphi_{x_x}$ is rendered by the unknown generalized eigenvalues $\lambda_x$ of $\Psi_x$ and $\mathbf{T}$, i.e. also $\lambda_x$ may be highly non-stationary. In contrast, due to the (inevitable) recursive averaging in (58), the computed generalized eigenvalues $\hat{\lambda}_x|_{\text{sm}}$ of $\hat{\Psi}_x|_{\text{sm}}$ and $\mathbf{T}$ are slowly time-varying if $\zeta$ is sufficiently large, i.e. non-stationarities are to some extent smoothed, and so would be PSD estimates based on $\hat{\lambda}_x|_{\text{sm}}$ or $\hat{\Psi}_x|_{\text{sm}}$. While smooth PSD estimates are commonly preferred in some applications (e.g. for perceptual reasons, in the computation of spectral gains in speech enhancement [2]), others may exploit non-stationarities (such as, e.g., the Kalman filter [33], where PSD estimates of the observation noise act as a regularization term in the recursive update of the state estimate [34]). Depending on the application, we therefore propose to restore non-stationarities by desmoothing $\hat{\lambda}_x|_{\text{sm}}$, yielding an estimate $\hat{\lambda}_x$ of $\lambda_x$.

To this end, we note that the recursive averaging in (58) may be considered an element-wise filtering operation with $x(l)x^H(l)$ as the input, $\hat{\Psi}_x|_{\text{sm}}(l)$ as the output, and the (allpole) z-domain transfer function given by $(1-\zeta)/(1-\zeta z^{-1})$. Therefore, in order to desmooth $\hat{\lambda}_x|_{\text{sm}}(l)$, we propose to apply the corresponding (all-zero) inverse transfer function given by $(1-\zeta z^{-1})/(1-\zeta)$ followed by non-negative thresholding, i.e.

$$\hat{\lambda}_x^e(l) = \frac{\hat{\lambda}_x|_{\text{sm}}(l) - \zeta \hat{\lambda}_x|_{\text{sm}}(l-1)}{1-\zeta},$$

(59)

$$\hat{\lambda}_x(l) = \max[\hat{\lambda}_x^e(l), 0],$$

(60)

where the thresholding in (60) avoids negative eigenvalue estimates, which otherwise may appear in a limited number of frames due to modeling and estimation errors. Note that the desmoothing operation requires the associated generalized eigenvalues in $\hat{\lambda}_x|_{\text{sm}}(l)$ and $\hat{\lambda}_x|_{\text{sm}}(l-1)$ to be sorted correspondingly. This may be ensured by sorting $\hat{P}(l)$ such that $P''(l-1)\hat{P}(l) \approx I$, cf. (53), and $\hat{\lambda}_x|_{\text{sm}}(l)$ accordingly, which can be done easily for large $\zeta$ and the therewith slowly time-varying GEVD [25]. Alternatively, recursive sorting may be avoided if the GEVD is estimated recursively, e.g., by means of the power method [35], [36]. One may then define the corresponding desmoothed estimate $\hat{\Psi}_x$ via its decomposition

$$\hat{\Psi}_x \hat{P} = \hat{\Gamma} \hat{\Lambda}_x,$$

(61)

with $\hat{\Lambda}_x = \text{Diag}[\hat{\lambda}_x]$, (62)

where $\hat{P}$ remains unchanged.

### C. Early Correlation Matrix Estimation and Factorization

Given $\hat{P}$ and $\hat{\Lambda}_x$ in (61)–(62), we now retrieve the subspace-based rank-$N$ estimates $\hat{\Psi}_x$ and $\hat{\Psi}_{x/2}$. To this end, based on (55)–(57), we note that $\lambda_x$ may be estimated as

$$\hat{\lambda}_x = [\hat{\lambda}_x]_{1:N} - \varphi_{x_x}1,$$

(63)

where $\varphi_{x_x}$ in turn may be obtained by averaging the last $M-N$ generalized eigenvalues in $[\hat{\lambda}_x]_{N+1:M}$, [14]. Considering (56)–(57), given $\hat{\Lambda}_x = \text{Diag}[\hat{\lambda}_x]$ from (63) and $\hat{P}^{-1} = \hat{P}^H\hat{T}$ from (53), we can define a rank-$N$ estimate of $\hat{\Psi}_x$ as

$$\hat{\Psi}_x = \hat{\Gamma} \hat{\Lambda}_x \hat{P} = \hat{\Gamma} \hat{\Lambda}_x [\hat{\Lambda}_x]^{\frac{1}{2}},$$

(64)

From (64), we can further easily derive a square root $\hat{\Psi}_{x/2}$ as

$$\hat{\Psi}_{x/2} = \hat{\Gamma} [\hat{\Lambda}_x]^{\frac{1}{2}},$$

(65)

with $\hat{\Lambda}_x^{\frac{1}{2}} = \text{Diag}[\hat{\lambda}_x^{\frac{1}{2}}]$, (66)

with arbitrary complex arguments of the elements in $\hat{\lambda}_x^{\frac{1}{2}}$.

Note that as opposed to the order presented in Sec. [V-B] and this section, we may also apply desmoothing only after obtaining a smooth estimate of the early correlation matrix and its square root, which showed to yield comparable results in our simulations.

### VI. SIMULATIONS

In this section, we compare the algorithms based on the conventional and the square-root MP as presented in Sec. [III] and Sec. [IV] respectively. We assume that an (initial) RETF estimate $\hat{H}$ is available, and that $\hat{\Psi}_x$ and $\hat{\Psi}_{x/2}$ are obtained as described in Sec. [V].

Apart from estimation errors in $\hat{\Psi}_x$, $\hat{\Psi}_{x/2}$, and $\hat{H}$, the performance of both algorithms is subject to modeling errors, cf. Sec. [II]. Unfortunately, due to the model deficiencies in [9]–[15], exact and observable ground truth early PSDs $\varphi_s$ and ground truth RETFs $\hat{H}$ do not exist in a practical setup based on realistic acoustic data. Therefore, in order to yield a broader understanding of the algorithms’ behavior, we perform two kinds of simulations. In the first kind, instead of generating time-domain data and estimating $\hat{\Psi}_x$ in the STFT domain, we generate $\hat{\Psi}_x = \Psi_x$ directly based on [9]–[14] and assumed geometric and physical properties, i.e. $\hat{\Psi}_x$ is free of modeling
and estimation errors. This way, we are able to define exact ground truth early PSDs $\varphi_s$ and ground truth RETFs $H$ that may be used to define exact performance measures. Further, the estimates $\Psi_x$ and $\hat{\Psi}_x^\perp$ obtained as described in Sec. [V] will be free of estimation errors, such that the performance of both algorithms depends on the RETF estimation error in $\hat{H}$ and the algorithmic settings in Sec. [III] and Sec. [IV] only. We refer to these simulations as the model-based-data case. In the second kind of simulations, we generate acoustic data in the time domain from recorded speech signals and measured room impulse responses (RIRs), and estimate $\Psi_x$ in the STFT domain. This way, the setup becomes more practical, however, evaluation becomes less trivial in terms of the definition of performance measures, such that we need to define and rely on an approximate ground truth early PSD $\varphi_s$ as a reference. We refer to these simulations as the acoustic-data case. The model-based-data case and the acoustic-data case are discussed in Sec. [VI-A] and Sec. [VI-B] respectively.

A. Model-based Data

We define our performance measures in Sec. [VI-A1] discuss the data-generation in Sec. [VI-A2] the algorithmic settings in Sec. [VI-A3] and the evaluation results in Sec. [VI-A4].

1) Performance Measures: We define the RETF estimation error,

$$E_H = \hat{H} - H,$$

(67)

where $i^\gamma E_H = [E_H]_N = 0^\gamma$ since both $H$ and $\hat{H}$ satisfy (6), and based on that the relative squared RETF estimation error,

$$\varepsilon_H = 10 \log_{10} \frac{\text{tr}[E_H^2]}{\text{tr}[\tilde{H}^2 H]} - N \text{ dB},$$

(68)

where we subtract $N$ in the denominator in order to compensate for the fact that the first row of $H$ is known. Since the early PSDs $\varphi_s$ are already a second-order property of the underlying signal $s$, we define the PSD estimation error with respect to the non-negative square root of $\tilde{\varphi}_s$ and $\varphi_s$, i.e.

$$e_{\varphi_s} = \sqrt{\varphi_s} - \sqrt{\tilde{\varphi}_s},$$

(69)

and based on that the relative squared PSD estimation error,

$$\varepsilon_{\varphi_s} = 10 \log_{10} \frac{e_{\varphi_s}^T e_{\varphi_s}}{1^T \varphi_s} \text{ dB},$$

(70)

2) Data Generation: Let $\tilde{\Psi}_x$ be available and free of modeling and estimation errors, i.e. we have $\Psi_x = \tilde{\Psi}_x$ with $\tilde{\Psi}_x$ adhering to (9)–(14). We generate $\tilde{\Psi}_x$ based on assumed geometric and physical properties. We assume a linear microphone array of $M = 5$ microphones with inter-microphone distance of $8 \text{ cm}$ and the speed of sound to be $340 \text{ m/s}$. Further, we assume $N = 3$ sources, positioned at $(-30, 0, 60)^\circ$ relative to the broadside direction of the microphone array. The RETFs $H$ are generated assuming omnidirectional microphones of equal gain as well as free- and far-field propagation for the early components, i.e. $H$ depends on the DoAs only and is fully defined by the corresponding phase shifts between microphones. The estimate $\hat{H}$ is generated by adding an error component $E_H$ according to (67), where the elements

![Fig. 1](image1.png)

Fig. 1: $\varepsilon_{\varphi_s}$ versus $\varepsilon_H$ for conventional MP and square-root MP with $\alpha = 10^3$ at $f = 2 \text{ kHz}$.

![Fig. 2](image2.png)

Fig. 2: $\varepsilon_{\varphi_s}$ versus $\alpha$ for conventional MP and square-root MP at $\varepsilon_H = -10 \text{ dB}$ and $f = 2 \text{ kHz}$.

$[\tilde{\Psi}_x]_{:2:M}$ are drawn from independent complex Gaussian distributions, yielding a particular $\varepsilon_H$ according to (68). The diffuse coherence matrix $\Gamma$ is computed assuming a spherical-isotropic sound field. The early PSDs $\varphi_s$ are generated in the following manner. We draw the real and imaginary parts of the elements of $s$ from independent Laplace distributions, which is a commonly assumed distribution for STFT coefficients of speech [37], [38], i.e. we have $\Re[s_n] \sim (1/b)e^{-2|\Re[s_n]|/b}$ and $\Im[s_n] \sim (1/b)e^{-2|\Im[s_n]|/b}$, where the scaling parameter $b$ is referred to as diversity. Then, we define $\varphi_s = \text{Diag}|s|^2$, i.e. $\varphi_s$ is the squared magnitude of $s$. Given the above, we set $\Psi_x = H\varphi_s H^\perp$ according to (10). Note that since $\Psi_x = \tilde{\Psi}_x$ is free of modeling errors, where $\Psi_x = \Psi_x + \Psi_x^\perp$ with $\Psi_x^\perp = \varphi_s \Gamma$, cf. (9) and (14), the component $\Psi_x^\perp$ may be perfectly estimated from $\tilde{\Psi}_x$ by means of the GEVD as described in Sec. [V-C] yielding $\tilde{\Psi}_x = \Psi_x$ independently of $\varphi_s$. Further, note that next to $H$ and $\tilde{\Psi}_x$, via the GEVD, also $\Gamma$ influences the shape of the square root $\tilde{\Psi}_x^{1/2} = \Psi_x^{1/2}$ in the sense of defining the basis for a given vector space, cf. Sec. [V-C] For each data-point in the evaluation, cf. Sec. [VI-A4] we simulate $2^{14}$ realizations of $\tilde{\Psi}_x^{1/2}$ and $\hat{\Psi}_x^{1/2}$.

3) Algorithmic Settings: In the model-based-data case, as opposed to the acoustic-data case, cf. Sec. [VI-B3] the sampling frequency and STFT-processing parameters are irrelevant since we generate $\tilde{\Psi}_x$ directly in the STFT-domain, cf. Sec. [VI-A2] Regardless, we simulate frequencies up to $f = 8 \text{ kHz}$, corresponding to a virtual sampling frequency of $f_s = 16 \text{ kHz}$. The soft-constraint penalty factor $\alpha$ in the conventional MP in (23) and the square-root MP in (24) is simulated in the range $\alpha \in [10^3, 10^6]$. We perform at most $i_{\text{max}} = 20$ iterations of the associated iterative algorithms in (24)–(25) and (35)–
larger improvements for higher values of $\alpha$ in the square-root MP. Recall that the soft constraint in the conventional MP is scalar-based, cf. (22), while the soft constraint in the square-root MP is vector-based, cf. (33), and is therefore more informative. The square-root MP outperforms the conventional MP by 2.5 dB at low values of $\alpha$, and by 5.7 dB at high values of $\alpha$. Interestingly, for both algorithms, despite $\hat{\Psi}_{x_s}$ and $\hat{\Psi}_{s/2}$ being free of estimation errors, the minimum of $\varepsilon_{\varphi}$ does not occur at the highest values of $\alpha$, but at around $\alpha = 10^3$. As compared to higher values, the improvement is however mild.

Fig. 3 illustrates $\varepsilon_{\varphi}$, for different frequencies $f$ for the conventional MP and the square-root MP with $\alpha = 10^3$ at (a) $\varepsilon_H = 0$ dB, (b) $\varepsilon_H = -10$ dB, and (c) $\varepsilon_H = -20$ dB. The graphs denote medians over all 214 realizations, cf. Sec. VI-A2 and the shaded areas denote the range from the first to the third quartile. As can be seen, for both the conventional MP and the square-root MP, $\varepsilon_{\varphi}$ increases at a rate of about 10 dB per 10 dB increase in $\varepsilon_H$ until roughly $\varepsilon_H = 0$ dB and $\varepsilon_H = 5$ dB is reached, respectively, after which $\varepsilon_{\varphi}$ begins to saturate. This saturation is due to the fact that both algorithms yield non-negative estimates $\varphi_s \geq 0$, which limits the estimation error at high values of $\varepsilon_H$. The square-root MP outperforms the conventional MP by at least 5.7 dB for $\varepsilon_H \leq 0$ dB, and by somewhat less for $\varepsilon_H \geq 5$ dB.

Fig. 4 demonstrates the effect in the median of the initial estimate $\hat{\varphi}_s^{1/2}(0)$ on the convergence behavior in terms of the relative squared PSD estimation error $\varepsilon_{\varphi}^{(i)}$ at iteration $i$ for different values of $\varepsilon_H$ of the iterative algorithm in (33)–(36) solving the square-root MP with $\alpha = 10^3$ at $f = 2$ kHz. The initial value is based on (a) the sum constraint in (13) as $\sqrt{\Psi_{x_s}}(0) = \sqrt{[\hat{\Psi}_{x_s}]_{1,1}/N}$, and (b) the estimator in (17)–(18), here denoted by $\hat{\varphi}_s(0)$, as $\hat{\varphi}_s^{1/2}(0) = \sqrt{\hat{\varphi}_s(0)}$. In both cases, the algorithm converges to almost the same final value.
of $\epsilon_{\varphi}$. However, we find that in (a), convergence is reached at around $i = 3$ to $i = 4$, while in (b), due to the improved initial estimate, convergence is reached at $i = 1$ already. Hence, while the computation of the initial estimate in (b) is somewhat more expensive, we save 2 to 3 iterations as compared to (a).

Fig. 5 demonstrates the recursive behavior in terms of (a) $\epsilon_{\varphi}(l + r)$ and (b) $\epsilon_{\varphi}(l + r)$ with $r$ the recursion index for the conventional MP and the square-root MP with $\alpha = 10^3$ at $f = 2$ kHz and $\epsilon_{\varphi}(l) = 0$ dB. Here, the source positioned at $-30^\circ$ transitions to $-40^\circ$ at $r = 32$, resulting in a transient change in the otherwise constant RETF $H$. While no update of the estimate $H$ is performed for the conventional MP, we do update $H$ recursively for square-root MP as described in Sec. IV-C. For the conventional MP, we expectably find that $\epsilon_{\varphi}(l + r)$ and $\epsilon_{\varphi}(l + r)$ remain constant except for a transient increase of 6.8 dB and 3.2 dB at $r = 33$, respectively. For the square-root MP, due to the recursive update of $H$, we find that $\epsilon_{\varphi}(l + r)$ and $\epsilon_{\varphi}(l + r)$ decrease by 5.2 dB and 4.7 dB over the course of the first 32 recursions, followed by an increase of 11.2 dB and 6.1 dB at $r = 33$, respectively, and a subsequent decrease at roughly the same rate.

### B. Acoustic Data

We define the performance measures in Sec. VI-B1 discuss the acoustic scenario in Sec. VI-B2 the algorithmic settings in Sec. VI-B3 and the evaluation results in Sec. VI-B4.

1) Performance Measures: In the acoustic-data case, due to the model deficiencies in (67)–(70), cf. Sec. II, exact and observable ground truth early PSDs $\varphi_s$ and ground truth RETFs $H$ do unfortunately not exist, and so the performance measures in (67)–(70) cannot be used. However, one may define approximate ground truth early PSDs $\hat{\varphi}_s$ as a reference for evaluation. To this end, given the source signals and RIRs of a particular acoustic scenario, cf. Sec. VI-B2, we convolve the source signals with only the early part of the RIR to the first microphone and transform to the STFT-domain, yielding $\tilde{s}$, and set $\hat{\varphi}_s = \text{Diag}[\tilde{s}^H]b$, i.e. $\hat{\varphi}_s$ is the squared magnitude of $\tilde{s}$. Note that the definition of the early part of the RIR is somewhat arbitrary due to the weighted and overlapping windows in the STFT-processing. For STFT windows of $N_{\text{STFT}}$ samples with 50% overlap, one may, e.g., choose the first $N_{\text{STFT}}$ or the first $N_{\text{STFT}}/2$ taps of the RIR. Here, we have chosen the first $N_{\text{STFT}}$ samples corresponding to 32 ms, cf. Sec. VI-B3.

In our setup, we have found that different choices result in quantitatively different performance, but not qualitatively different conclusions.

Given a segment of $L$ frames of $\hat{\varphi}_s$ and $\hat{\varphi}_s$, we decompose $\sqrt{\varphi_s}$ according to (24) as

$$
\sqrt{\varphi_s} = \sqrt{\varphi_s} + e_{\text{int}}^\varphi + e_{\text{art}}^\varphi,
$$

where $\sqrt{\varphi_s}$ is the component of $\sqrt{\varphi_s}$ associated to $\sqrt{\varphi_s}$, i.e. the correctly estimated component, $e_{\text{int}}^\varphi = [e_{\text{int}}^\varphi]^T$, contains components associated to $\sqrt{\varphi_s}$, with $n' \neq n$, i.e. erroneously estimated leakage or interference components across sources, and $e_{\text{art}}^\varphi = [e_{\text{art}}^\varphi]^T$ contains components not associated to any $\sqrt{\varphi_s}$, i.e. erroneously estimated artifact components. Exemplary spectrograms illustrating the decomposition in (71) are shown in Fig. 6, cf. also the discussion in Sec. VI-B4.

Given $L$ frames of $\sqrt{\varphi_s}$, $e_{\text{int}}^\varphi$, and $e_{\text{art}}^\varphi$, we define the signal-to-interference ratio $SIR(\kappa)$, the signal-to-artifacts ratio $SAR(\kappa)$, and the signal-to-distortion ratio $SDR(\kappa)$ per third-octave band $\kappa$ along the lines of (24) as

$$
SIR(\kappa) = 10 \log_{10} \frac{\sum_{k,l} \| \sqrt{\varphi_s}(k,l) \|^2_2}{\sum_{k,l} \| e_{\text{int}}^\varphi(k,l) \|^2_2},
$$

$$
SAR(\kappa) = 10 \log_{10} \frac{\sum_{k,l} \| \sqrt{\varphi_s}(k,l) + e_{\text{art}}^\varphi(k,l) \|^2_2}{\sum_{k,l} \| e_{\text{art}}^\varphi(k,l) \|^2_2},
$$

$$
SDR(\kappa) = 10 \log_{10} \frac{\sum_{k,l} \| \sqrt{\varphi_s}(k,l) \|^2_2}{\sum_{k,l} \| e_{\text{int}}^\varphi(k,l) + e_{\text{art}}^\varphi(k,l) \|^2_2},
$$

with $k = k_\omega, \ldots, k_\omega$ and $k_\omega$ and $k_\omega$ the frequency-bin indices of the lower and upper band limits of third-octave-band $\kappa$, and $l = 0, \ldots, L - 1$.

The decomposition in (71) relies on a segment of $L$ frames of $\hat{\varphi}_s$ and $\hat{\varphi}_s$, and is done in the following manner. Let $\hat{\varphi}_s$ be a vector stacking the early PSD estimates $\hat{\varphi}_s$, of source $n$ over $L$ observed frames, i.e. $\hat{\varphi}_s = (\hat{\varphi}_s(0) \cdots \hat{\varphi}_s(L - 1))^T$, and let $\bar{\varphi}_s, \bar{\varphi}_s, \bar{\varphi}_s$ and $\bar{\varphi}_s$ be defined equivalently, such that $\sqrt{\varphi_s} = \sqrt{\bar{\varphi}_s} + e_{\text{int}}^\varphi + e_{\text{art}}^\varphi$. Then, we perform the orthonormal projection of each individual vector $\sqrt{\varphi_s}$ onto the one-dimensional subspace spanned by the corresponding vector $\sqrt{\bar{\varphi}_s}$, yielding $\sqrt{\bar{\varphi}_s}$ with $\sqrt{\bar{\varphi}_s} \propto \sqrt{\bar{\varphi}_s}$, as well as onto the $N$-dimensional subspace spanned by all $N$ vectors $\sqrt{\varphi_s}$, yielding $\sqrt{\bar{\varphi}_s} + e_{\text{int}}^\varphi$, which then allows us to explicitly compute $e_{\text{int}}^\varphi$ and $e_{\text{art}}^\varphi$.

2) Acoustic Scenario: We use RIRs of 0.61 s reverberation time to a physical linear microphone array of $M = 5$ microphones with an inter-microphone distance of 8 cm [39], similar to the assumed microphone array in Sec. VI-A2. We simulate $N = 2$ sources, using female and male speech [40] as source signals. The sources are assigned to two out of three possible source positions in 2 m distance of the microphone array at
While we do not update \( \hat{s}_n \) of the associated iterative algorithms in (24)–(25) and (35)–(36). In the latter case, in (49), since we update \( \hat{s}_n \) in Sec. IV, namely first where we do not update \( \hat{s}_n \), and the square-root MP in (34) is simulated in the range \( \alpha \in [10^{-3}, 10^3] \). We perform at most \( i_{\text{max}} = 20 \) iterations of the associated iterative algorithms in (24)–(25) and (35)–(36). While we do not update \( \hat{H} \) for the conventional MP in Sec. III, we consider two cases for the square-root MP in Sec. IV, namely first where we do not update \( \hat{H} \), and second where we update \( \hat{H} \) recursively as described in Sec. IV-C.

In the latter case, in (49), since \( \hat{\Psi}_x \) is subject to modeling and estimation errors and contains residual late reverberation, we set \( \varphi_{\text{reg}} = \hat{\varphi}_x \). In (50), the threshold \( \xi_{\text{th}} \) is again set as \( 10 \log_{10} \xi_{\text{th}} = -2 \) dB and \( \beta \) is set per third-octave band \( \kappa \) as \( \beta(\kappa) = 20 \beta^2(\kappa) \), with \( \beta(\kappa) \) pre-defined as the diversity of the Laplace distributions fitted to the real and imaginary parts of the STFT coefficients of a training signal within third-octave band \( \kappa \). Here, the training signal is generated from the entire female and male speech source signals, cf. Sec. VI-B2 by convolving the early part of the RIR of the first microphone corresponding to a source at 2 m distance at 0° relative to the broadside direction, cf. also the similar segment-wise definition of the reference signal \( \hat{s}_n \) in Sec. VI-B1. Note that while \( \beta(\kappa) \) is pre-computed using all STFT coefficients of both male and female speech within third-octave band \( \kappa \), the actual distributions may vary across speakers, across source positions, across individual frequency bins, and across individual segments, cf. also Sec. VI-B2.

4) Results: Before discussing the performance of the conventional MP and the square-root MP in terms of the measures SIR, SAR, and SDR, we first consider the exemplary spectrograms in Fig. 6 visualizing the decomposition of \( \sqrt{\varphi_s} \) upon which these measures are based. In this example, the microphone signals \( x \) and the reference PSDs \( \hat{\varphi}_s \) and \( \hat{\varphi}_s \) originate from a female and a male speaker at −30° and 60°, respectively, and the estimate \( \hat{s}_n \) is obtained by means of the square-root MP.

![Exemplary spectrograms depicting \( \hat{\varphi}_s \) in (a.1), \( \hat{\varphi}_s \) in (b.1), \( \hat{\varphi}_s^{\text{2int}} \) in (c.1), and \( \hat{\varphi}_s^{\text{2int}} \) in (d.1), with \( \hat{\varphi}_s \), \( \hat{\varphi}_s^{\text{2int}} \), and \( \hat{\varphi}_s^{\text{2int}} \) obtained from the decomposition of \( \sqrt{\varphi_s} \), cf. Sec. VI-B1. The reference PSDs \( \hat{\varphi}_s \) and \( \hat{\varphi}_s \) originate from a female and a male speaker at −30° and 60°, respectively, and the estimate \( \hat{s}_n \) is obtained by means of the square-root MP.](image-url)
Finally, the artifact components $e^{2\mathrm{art}}_{2^{\mathrm{art}}}$ in Fig. 6(d.1) and Fig. 6(d.2) do not relate to any of the reference PSDs, but rather to residual late reverberation in the estimate $\Psi_{2^{\mathrm{art}}}$, cf. also Sec. V-C, which is due to modeling errors in (9)-(14) and a potential deviation of the late reverberant sound field from the spatial coherence matrix $\Gamma$. Note that in $e^{2\mathrm{art}}_{2^{\mathrm{art}}}$, the energy is concentrated in the same spectro-temporal regions, indicating a similar spatial sound field of these components.

Fig. 7 shows the median over all segments and speaker-source-combinations, cf. Sec. VI-B2 of (a) SIR, (b) SAR, and (c) SDR in third-octave bands for the conventional MP [■], the square-root MP without recursive RETF update [□], and the square-root MP with recursive RETF update [▲]. Here, in each third-octave band $\kappa$, we have selected $\alpha(\kappa)$ such that $SIR(\kappa)$ is maximized for each algorithm, i.e. the figure indicates their upper performance limit in terms of $SIR(\kappa)$ with respect to the tuning of $\alpha(\kappa)$. Note that in our setup, selecting $\alpha(\kappa)$ to maximize $SAR(\kappa)$ or $SDR(\kappa)$ does not lead to qualitatively substantial differences. For the conventional MP, we have found values of $\alpha(\kappa) \ll 1$ to be preferable in all third-octave bands $\kappa$, indicating that the soft-constraint penalty in (23) is not very useful in practice. For the square-root MP, with and without recursive update, we have found $\alpha(\kappa) \gg 1$ to be preferable in third-octave bands below 0.5 kHz, and $\alpha(\kappa) \leq 1$ to be preferable above 0.5 kHz. From Fig. 7(a), we find that the square-root MP clearly outperforms the conventional MP in terms of $SIR$ in third-octave bands above 0.25 kHz, with improvements of 1 dB to 6 dB, indicating better source-component separation performance. Further, for the square-root MP, we find that the recursive RETF update mildly improves the performance by up to 1 dB. Recall that the initial RETF estimate $\hat{H}$ is based on the correct DoAs, but does not consider early reflections, cf. Sec. VI-B3. From Fig. 7(b), we note that for all algorithms, we have $SAR(\kappa) < SIR(\kappa)$ in third-octave bands above 0.5 kHz, indicating comparably strong residual late reverberation. The square-root MP performs slightly worse than the conventional MP in terms of $SAR$ in third-octave bands above 0.25 kHz, with degradations of less than 1 dB. In the square-root MP, recursive RETF updating results in minor differences only. As can be seen from Fig. 7(c), we find that the square-root MP outperforms the conventional MP in terms of $SDR$, however, due to the comparably strong residual late reverberation, by much less than in terms of $SIR$. Again, in the square-root MP, recursive RETF updating results in minor differences only.

VII. CONCLUSION

We have discussed early PSD estimation in the STFT domain for multiple sources in reverberant environments, based on a commonly used multi-microphone correlation matrix model, given (initial) RETF estimates. State-of-the-art approaches to early PSD estimation formulate a minimization problem on the approximation error with respect to an estimate of the early correlation matrix, referred to as conventional MP. Instead, we here have factorized the early correlation matrix model and formulated a corresponding minimization problem on the approximation error with respect to an estimate of the early-correlation-matrix square root, which we referred to as the square-root MP. The square-root MP seeks a unitary matrix and the square roots of the early PSDs up to an arbitrary complex argument, and therewith constitutes a generalization of the orthogonal Procrustes problem. As opposed to the conventional MP, non-negative inequality constraints are not required in the square-root MP. The square-root MP may be solved iteratively, requiring one SVD per iteration. Based on the estimated unitary matrix and early PSD square roots, we are further able to recursively update the RETF estimate, which is not inherently possible in the conventional approach. The respectively required estimates of the early correlation matrix and the early-correlation-matrix square root may be obtained from an estimate of the microphone signal correlation matrix by means of the GEVD. Hereat, in order to compensate for inevitable recursive averaging, we have restored non-stationarities by desmoothing the generalized eigenvalues.

In order to evaluate the proposed approach, we have performed two kinds of simulations. In the first kind, the data is generated based on the microphone signal correlation matrix model and assumed geometric and physical properties, excluding modeling errors from the evaluation. This is referred to as model-based-data case. In the second kind, the data is generated from recorded speech and measured RIRs, creating a more practical setup. This is referred to as acoustic-data case. In the model-based-data case, the simulation results indicate better performance of the square-root MP as compared to the conventional MP in terms of the relative squared PSD estimation error. If initialized accordingly, the square-root MP can be solved in only one iteration. In the acoustic-data case...
case, the simulation results indicate better performance of the square-root MP as compared to the conventional MP in terms of the source-component separation measured by the signal-to-interference ratio. Both the square-root MP and the conventional MP suffer somewhat from residual late reverberation in the early-correlation-matrix estimate.
