Abstract

Objective: To evaluate the perioperative clinical efficacy of preoperative human fibrinogen treatment in patients with acute Stanford type A aortic dissection (ATAAD).

Methods: Data of 159 patients with ATAAD who underwent emergency surgical treatment in our hospital from January 2019 to December 2020 were retrospectively analyzed. Patients were divided into two groups according to whether human fibrinogen was administered before surgery; patients in group A received fibrinogen before surgery, while those in group B did not. The preoperative clinical data, surgical data, postoperative data, complications related to the coagulation function, and mortality of the two groups were compared and analyzed.

Results: The in-hospital mortality was similar in the two groups (2.9% vs. 9.3%, p = .122). However, group A had a significantly shorter operation time (279.24 ± 39.03 vs. 298.24 ± 45.90, p = .008), lower intraoperative blood loss (240.48 ± 96.75 vs. 353.70 ± 189.80, p < .001), and reduced intraoperative transfusion requirement of red blood cells (2.61 ± 1.18 vs. 6.05 ± 1.86, p < .001). The postoperative suction drainage within 24 h in group A was significantly decreased (243.24 ± 201.52 vs. 504.22 ± 341.08, p = .002). The incidence of postoperative acute kidney injury (AKI) in group A was lower than that in group B (3.8% vs. 14.8%, p = .023). Similarly, the incidence of postoperative hepatic insufficiency in group A was lower than that in group B (1.9% vs. 9.3%, p = .045). In group A, the mechanical ventilation time was shorter (47.68 ± 28.61 vs. 118.21 ± 173.16, p = .004) along with reduced intensive care unit stay time (4.06 ± 1.18 vs. 8.09 ± 9.42, p = .003), and postoperative hospitalization days (19.20 ± 14.60 vs. 23.50 ± 7.56, p = .004).

Conclusion: Preoperative administration of human fibrinogen in patients undergoing ATAAD surgery can effectively reduce the intraoperative blood loss, amount of...
Blood transfused, operation time, and postoperative complications, and improve the early prognosis of patients. In addition, this procedure is highly safe.

acute Stanford type A aortic dissection, clinical application value, coagulation dysfunction, human fibrinogen

1 | INTRODUCTION

Aortic dissection (AD) is a life-threatening condition, and acute Stanford type A aortic dissection (ATAAD) carries the highest mortality among all AD types. Studies have shown that mortality from AD is highest in the first 48 h after the onset of symptoms, which can be more than 50%, and the highest mortality within 2 weeks can be more than 80%. Therefore, the primary management of ATAAD is emergency surgery, which is the only effective treatment. Despite the continual improvement in surgical techniques, the rates of surgical complications, morbidity, and mortality remain high.

Bleeding is one of the most common complications after ATAAD. Bleeding complications with ATAAD have not been adequately evaluated yet. Previous studies have shown that ATAAD can cause coagulation disorders. Several studies have shown that patients with ATAAD have significant coagulation/fibrinolysis abnormalities before surgery. Preoperatively, when the blood flows through the pseudolumen of nonendothelial tissue in patients with AD, it comes in contact with the damaged tissue, leading to turbulence. These factors can effectively activate the coagulation/fibrinolytic system and platelets, resulting in the formation of thrombi and consumption of large amounts of clotting factors. Simultaneously, the inflammatory system is activated, and platelets are an important link to start the inflammatory response cascade. Many factors lead to the consumption of platelets in large quantities, thus reducing the number of platelets. Some researchers have shown that the degree of postoperative damage to coagulation factors and fibrinogen is greater than the degree of damage to platelet function. Therefore, fibrinogen plays an important role in the occurrence and development of AD. Cardiopulmonary bypass (CPB) surgery further leads to dysfunction of the body’s coagulation and fibrinolytic system, resulting in clotting-related complications. This can lead to increased postoperative blood loss, increased perioperative blood product infusion, increased incidence of vital organ complications, and death.

Therefore, in this study, patients with ATAAD who received fibrinogen as preoperative intravenous infusion were evaluated to explore the effect of fibrinogen on the prognosis of patients with intraoperative bleeding and postoperative bleeding-related complications, with the aim of providing a relevant theoretical basis for clinical treatment.

2 | METHODS

2.1 | Patient population and data collection

A retrospective analysis was performed on 159 ATAAD patients admitted to the Department of Cardiac Surgery, Union Hospital, Fujian Medical University from January 2019 to December 2020. Preoperative thoracic and abdominal aortic computed tomographic angiography and cardiac echocardiography were performed in all patients to clarify the diagnosis and scope of the lesion. Preoperative basic information of the patients in groups A and B is shown in Table 1. Intraoperative surgical methods are shown in Table 2. Inclusion criteria was within 2 weeks of onset. Exclusion criteria were as follows: (1) previous severe respiratory disease, nervous system disease, hematologic disease, severe pulmonary infection, thrombotic disease, abnormal liver, and kidney function; (2) patients with cardiac insufficiency, massive pericardial effusion, coronary heart disease, cerebrovascular accident, and obvious organ or limb malperfusion (including poor lower limb perfusion, brain perfusion, coronary artery perfusion, and visceral perfusion); and (3) patients with ongoing anticoagulant and dual antiplatelet treatment.

Based on the preoperative use of Human Fibrinogen (Production enterprise: Green Cross [China] Biological Products Co., LTD; Approval Number: S20003011 [2 g human fibrinogen intravenous drop]), patients were divided into two groups: group A consisted of 105 patients who received intravenous human fibrinogen before the operation, while group B consisted of 54 patients who did not receive human fibrinogen before the operation. There were no significant differences in sex, age, body weight, hypertension, preoperative fibrin level, and intraoperative operative procedures between the two groups, and the data of the two groups were comparable. This study was approved by the ethics committee of Union Hospital, Fujian Medical University and conformed to the Declaration of Helsinki. And this retrospective review of patient data did not require written informed consent from participants in accordance with national guidelines.

Preoperative baseline data of the two groups were retrospectively recorded and statistically analyzed. Intraoperative data related to the operation, including operation time, CPB time, aortic clamp time, selective cerebral perfusion (SCP), low body arrest time, infusion of red blood cells, infusion of fresh frozen plasma, infusion of platelets, postoperative suction drainage within 24 h, rethoracotomy for hemostasis, mechanical ventilation time, intensive care unit (ICU) stay time, postoperative hospital stay, incidence of vital organ complications.
including multiorgan dysfunction, acute kidney injury [AKI], hepatic insufficiency, gastrointestinal hemorrhage, cerebral infarction, cerebral hemorrhage), and 30-day mortality rate were analyzed.

2.2 | Statistical analysis

Analyses were conducted using SPSS® software (IBM® Corporation). Data are presented as mean ± standard deviation (SD), or median (25th, 75th quartiles). Fisher’s exact test was applied for categoric variables, and the Mann–Whitney U test or Kruskal–Wallis test was applied for continuous variables. Univariate analysis and multivariate analyses were used to determine risk factors. Categorical data are given as the counts and percentage (n, %). A minimum p value of .05 was considered to be statistically significant.

2.3 | Results

There was no significant difference in the preoperative baseline data between the two groups (p > .05), and the data of the two groups were comparable.

1. Group A had a significantly shorter operation time (279.24 ± 39.03 vs. 298.24 ± 45.90, p = .008), reduced intraoperative blood loss (240.48 ± 96.75 vs. 353.70 ± 189.80, p < .001), and reduced intraoperative transfusion of red blood cells (2.61 ± 1.18 vs. 6.05 ± 1.86, p < .001). There was no difference in the CPB time, aortic clamp time, SCP, and low body arrest time between the two groups (p > .05).

2. The postoperative suction drainage within 24 h in group A was significantly decreased (243.24 ± 201.52 vs. 504.22 ± 341.08, p = .002). The incidence of postoperative AKI in group A was lower than that in group B (3.8% vs. 14.8%, p = .023). Similarly, the incidence of postoperative hepatic insufficiency in group A was lower than that in group B (1.9% vs. 9.3%, p = .045). In group A, the mechanical ventilation time was shorter than in group B (47.68 ± 28.61 vs. 118.21 ± 173.16, p = .004), along with a shorter ICU stay time (4.06 ± 1.18 vs. 8.09 ± 9.42, p = .003 ) and fewer postoperative hospitalization days (19.20 ± 14.60 vs. 23.50 ± 7.56, p = .004) (Table 3).

3. The in-hospital mortality was similar in the two groups (2.9% vs. 9.3%, p = .122) (Table 3).

3 | DISCUSSION

Acute aortic dissection (AAD) is a rare and life-threatening condition in which the blood flows from a tear in the intima of the aorta into the middle layer of the aorta. Untreated patients have a mortality rate of
1%–2% per hour after symptom onset. Prompt diagnosis and treatment can increase a patient's chances of survival and prevent serious complications. The survival rate of patients with acute AD is related to the timing of treatment, presence of end-organ dysperfusion, degree of aortic repair, and development of postoperative complications. ATAAD is a critical condition associated with high early surgical mortality rates, partly owing to bleeding complications. Previous studies on surgery for ATAAD have shown

| Valuables | Group A (n = 05) | Group B (n = 54) | p value |
|-----------|-----------------|-----------------|---------|
| Surgical procedures | | | |
| Sun's procedure, n (%) | 11 (10.5%) | 6 (11.1%) | .902 |
| Ascending aorta replacement + hemiarch replacement + a triple branched stent graft implantation, n (%) | 34 (32.4%) | 15 (27.8%) | .552 |
| Aortic valve-sparing + ascending aorta replacement + hemiarch replacement + a triple branched stent graft implantation, n (%) | 45 (42.9%) | 26 (48.1%) | .525 |
| Bentall + ascending aorta replacement + hemiarch replacement + a triple branched stent graft implantation, n (%) | 15 (14.3%) | 7 (13.0%) | .819 |
| Operative time (min) | 279.24 ± 39.03 | 298.24 ± 45.90 | .008 |
| CPB time (min) | 133.92 ± 39.39 | 131.74 ± 30.37 | .722 |
| Aortic clamp time (min) | 43.27 ± 12.06 | 43.76 ± 21.05 | .874 |
| SCP and low body arrest time (min) | 11.77 ± 3.06 | 12.89 ± 4.54 | .067 |
| Intraoperative blood loss (ml) | 240.48 ± 96.75 | 353.70 ± 189.80 | < .001 |
| Infusion of red blood cell (unit) | 2.61 ± 1.18 | 6.05 ± 1.86 | < .001 |
| Infusion of fresh frozen plasma (ml) | 41.43 ± 96.69 | 54.61 ± 100.13 | .422 |
| Infusion of platelet (unit) | 0.13 ± 0.31 | 0.12 ± 0.32 | .832 |

Note: Continuous normally distributed variables were expressed as mean ± standard deviation (SD) and categorical data are given as the counts and percentage (n, %).

| Valuables | Group A (n = 105) | Group B (n = 54) | p value |
|-----------|-----------------|-----------------|---------|
| Suction drainage within 24 h (ml) | 243.24 ± 201.52 | 504.22 ± 341.08 | .002 |

Abbreviation: AKI, acute kidney injury; ICU, intensive care unit.

1%–2% per hour after symptom onset. Prompt diagnosis and treatment can increase a patient's chances of survival and prevent serious complications.17–19 The survival rate of patients with acute AD is related to the timing of treatment, presence of end-organ dysperfusion, degree of aortic repair, and development of postoperative complications. ATAAD is a critical condition associated with high early surgical mortality rates, partly owing to bleeding complications.16 Previous studies on surgery for ATAAD have shown
that there is an activation of the coagulation system along with consumption coagulopathy. 21–23

Prolongation of the prothrombin time occurs owing to a reduction in one or more coagulation factors and the formation of fibrin and fibrinogen degradation products. Coagulopathy may result from the release of clotting substances from the aortic wall into the circulation, or from the accumulation of clotting factors at the site of the lesion, secondary to local exposure of the tissue factors in the torn arterial wall. Recent studies by Straub and Kessler have shown that local deposition of fibrinogen at the aneurysm site plays an important role in causing coagulation disorders. 24 Baumgartner et al. reported that the aortic adventitia possesses a high fibrinolytic activator activity, whereas the aortic media and intima possess weak thromboplastic properties. Moreover, the exposure of subendothelial aortic tissues has been shown to lead to significant deposition of platelets. 25 AD may be associated with a third pathway leading to coagulation abnormalities, which is activated by fibrinolytic activators present in the outer aortic membrane. Plasminase formation through this pathway leads to proteolysis of coagulation factors V, VIII, XII, and fibrinogen, resulting in the formation of fibrinogen and/or degradation products of fibrin.

During the development of AD, blood flows through the pseudolumen of nonendothelial tissue and comes in contact with the damaged tissue, thus leading to turbulence. These factors can effectively activate the coagulation system, fibrinolytic system, and platelets. The coagulation system is activated, resulting in a hypercoagulable state along with thrombin generation, thrombosis formation, and consumption of a large number of coagulation factors. Among them, fibrinogen is transformed into fibrin through the action of thrombin, which plays a role in hemostasis and the common coagulation pathway, and participates in a series of pathological and physiological processes in the body, such as inflammation and tissue damage and repair. 26

As a key component of blood clots, fibrinogen plays an important role in hemostasis and thrombosis. 27 Some studies have shown that fibrinogen plays an important role in hemostasis and thrombosis in patients with cardiovascular disease. 28,29 Fibrinogen can be used as a prognostic indicator of ATAAD, and a low fibrinogen level at admission is an independent predictor of in-hospital mortality in patients with ATAAD. 30 Other studies have shown that AAD activates the coagulation system before surgery, and the operation and intraoperative deep hypothermia can lead to a decrease in coagulation factors, platelet count, and function, as well as the fibrinogen concentration and function. 31–33 After hemostatic therapy, although the platelet count remains low, coagulation factors and platelet function return close to the preoperative level, 22 however, the fibrinogen concentration and function remain significantly lower than that at the preoperative level. Fibrinogen level is also an important predictor of bleeding. For each 1 g/L reduction in fibrinogen, the risk of bleeding increases 2.63 times. 34

The results of this study show that in patients with ATAAD with low fibrin level, preoperative human fibrinogen supplementation could significantly shorten the operation time, reduce the intraoperative blood loss and suction drainage within 24 h, as well as decrease the incidence of postoperative AKI and hepatic insufficiency. It was found to not only significantly reduce intraoperative and postoperative blood loss, but also play an important role in the patients’ postoperative recovery. Furthermore, it can significantly reduce postoperative organ dysfunction, and shorten the duration of ventilator use, ICU treatment, and postoperative hospital stay, but has little effect on mortality at 30 days after surgery. Some researchers have shown that there is no correlation between a low fibrinogen level and in-hospital mortality, and that a preoperative low fibrinogen level is the preferred indicator for predicting clinical complications in patients with ATAAD. 30,35

It has been shown that coagulation factors and fibrinogen are significantly reduced in AAD. Studies using enzyme-linked immunosorbent assay and thromboelastogram have also revealed a continuous activation of the coagulation system and depletion of coagulation factors, and that the degree of postoperative loss of coagulation factors and fibrinogen was greater than that of platelet function. 22 The importance of fibrinogen in reducing blood loss and saving lives is being increasingly emphasized. Both CPB and hypothermia can reduce fibrinogen synthesis and affect platelet function. With the availability of fibrinogen concentrate, many European guidelines recommend early infusion of fibrinogen concentrate to correct coagulation disorders. 36,37 Therefore, we suggest that hemostatic therapy should focus on early, rapid, and adequate supplementation of coagulation factors and fibrinogen to improve the levels of consumable coagulation factors in patients with acute AD. 25

In conclusion, AD is characterized by a unique coagulation system change process, and a large number of studies have confirmed that there are pathological changes in the coagulation and fibrinolytic system functions after the onset of AD. Our study results suggest that preoperative preventive fibrinogen supplementation can significantly shorten the operation time, reduce intraoperative and postoperative blood loss, reduce the probability of postoperative organ dysfunction, and shorten the time of ventilator use, ICU treatment, and postoperative hospital stay in patients with AD. Therefore, its clinical guiding significance for postoperative treatment, outcome, and prognosis of AD cannot be ignored. At present, the mechanism of coagulation and fibrinolytic system changes in patients with AD is not clear. Further studies on the underlying molecular signaling mechanisms may provide a new theoretical basis for the occurrence and development of AD, and provide new targets for clinical treatment.

4 | LIMITATIONS

This preliminary study has several limitations. One was the small sample that was retrospectively analyzed; however, it still has relevant statistical value. Based on the experience of the past 2 years and the results of this study, the author has designed a retrospective single-center controlled trial to determine whether preoperative use of fibrinogen in patients with ATAAD has clinical application value. All patients were administered the same dose, but there may be bias between different patients, as there is no standard
treatment regimen and individualized preoperative treatment was administered to different patients. We excluded patients with cardiac insufficiency, massive pericardial effusion, coronary atherosclerotic heart disease, cerebrovascular accident, and organ or limb malperfusion, which may have led to bias in the results. Therefore, further prospective randomized controlled studies are required.

5 | CONCLUSIONS

Preoperative use of human fibrinogen can reduce intraoperative blood loss and red blood cell transfusion requirement in patients undergoing surgery for ATAAD, in addition to shortening the operation time, reducing postoperative complications, and improving the early prognosis of patients, and being highly safe.
