Data deposition: This project has been deposited at EMBL/GenBank under the accession numbers CBLX010000001–CBLX010000027 for Asaia platycodi genome and CBLY010000001–CBLY010000009 for Saccharibacter sp. genome.

Abstract

Acetic acid bacteria (AAB) live in sugar rich environments, including food matrices, plant tissues, and the gut of sugar-feeding insects. By comparing the newly sequenced genomes of Asaia platycodi and Saccharibacter sp., symbionts of Anopheles stephensi and Apis mellifera, respectively, with those of 14 other AAB, we provide a genomic view of the evolutionary pattern of this bacterial group and clues on traits that explain the success of AAB as insect symbionts. A specific pre-adaptive trait, cytochrome bo3 ubiquinol oxidase, appears ancestral in AAB and shows a phylogeny that is congruent with that of the genomes. The functional properties of this terminal oxidase might have allowed AAB to adapt to the diverse oxygen levels of arthropod guts.

Key words: symbiosis, acetic acid bacteria, cytochrome oxidase.

Introduction

Besides plant tissues and food matrices, acetic acid bacteria (AAB) live in symbiosis with insects (reviewed in Crotti et al. 2010). Several research teams have investigated the relationship between AAB and their host (Crotti et al. 2010) focusing on the insect gut. In addition to the intestine, AAB could also be localized in other insect body compartments. For instance, the acetic acid bacterium Asaia colonizes not only the gut but also the salivary glands and the male and female reproductive systems, which are crucial sites for the bacterial transmission by horizontal and vertical routes (Damiani et al. 2008; Crotti et al. 2009; Gonella et al. 2012). Studies aiming to understand the nature of AAB symbiosis focused on the role of or potential advantages given by AAB to their respective hosts (Ryu et al. 2008; Chouaia et al. 2012; Mitraka et al. 2013) affecting the expression of genes related to the cuticle formation (Mitraka et al. 2013). In Drosophila, AAB are involved in the modulation of innate immunity, which keeps pathogenic strains under control (Ryu et al. 2008). Moreover, in the same host, Acetobacter pomorum modulates the insulin signaling, a pathway involved in the regulation of development, body size, energy metabolism, and intestinal stem cell activity of the host (Shin et al. 2011).

There are actually 14 genomes of AAB deposited in the databases but a genomic analysis of the evolutionary factors driving the association with insects is lacking. By including novel genome sequences of two AAB, Asaia platycodi and Saccharibacter sp., respectively, isolated from the malaria vector Anopheles stephensi and the honeybee Apis mellifera,
we present a genomic evolutionary analysis of AAB for assessing traits associated with the success of some of their members as insect symbionts. We discuss the potential role of alternative terminal oxidases as symbiotic factors favoring the adaptation of AAB to the insect hosts.

Results and Discussion

Several Potential Symbiotic Traits Are Present in AAB

Annotation of the A. platycodi and Saccharibacter sp. genomes revealed a series of traits compatible with a symbiotic lifestyle in the insect gut. Asaia platycodi and Saccharibacter present several secretion system (Sec-SRP and Tat for both genomes and type IV in the case of A. platycodi) and ABC transporters (in the case of A. platycodi) that may have roles in the cross talk between the bacterium and the host. A series of bacterial components for motility and cell surface structures can be implicated in the colonization of the gut epithelium by A. platycodi and Saccharibacter. These include the genes for the flagellar machinery (e.g., MotA, MotB, FlaA, FlaB, FlgC, FlgD, FlgE2, FlgH, FtsI) as well as genes encoding for fimbriae (sF-Chap and sF-UshP) and glycan biosynthesis. Although these features may help in the establishment of a symbiotic relationship, they are not essential for it. The presence of these traits was not associated with the ability to establish symbiosis. In fact, genes for the flagellar machinery were also present in Ac. aceti, Gluconacetobacter diazotrophicus, Gluconobacter frateurii, G. oxydans, and G. thailandicus but not Ac. pomorum and Comammimonas intimae. This trend was also observed for the other traits.

Both genomes contain the operon for the production of acetoin and 2,3-butanediol: These molecules have been shown to play a role in insects’ pheromone signaling (Tolash et al. 2003). 2,3-Butanediol has been implicated in the modulation of the innate immunity response of vertebrate hosts, facilitating tissue colonization by pathogenic bacteria (Bari et al. 2011). We can thus speculate that the production of metabolites potentially interfering with insect physiology and innate immunity might have provided AAB with a pre-adaptive feature toward symbiosis with insect hosts. This trait was observed in other AAB including most of those described as insect symbionts (i.e., Ac. tropicalis, C. intestini, Gluconacetobacter diazotrophicus, Gluconacetobacter europaeus, Gluconacetobacter oboediens, G. frateurii, G. morbiere, G. Oxydans, and G. thailandicus).

Adaptation to Diverse Oxic Conditions

AAB are aerobic organisms, consistent with their lifestyle in oxygen rich environments (Kersters et al. 2006). On the other hand, the oxygen levels in the guts of many arthropods may vary from aerobic to completely anoxic (Sudakaran et al. 2012). We have thus focused our attention on the presence and distribution of the oxygen-reacting systems of the electron transport chain (terminal oxidases). The genomes of both A. platycodi and Saccharibacter sp. present all the genes for the operons of cytochrome bo3 (GyoA-D) and bd (CydAB) ubiquinol oxidase, which have high affinity for oxygen. The operons of both cytochrome bo3 and bd oxidase are present in all AAB genomes, often with two different versions for the bd oxidase. This implies that both A. platycodi and Saccharibacter sp., as well as all the other AAB, have the capacity to respire through an aerobic respiratory chain independent from the terminal cytochrome aa3 oxidase, an enzyme with low affinity for oxygen, that is absent in AAB. Therefore, AAB have the potential to thrive at low oxygen concentrations like the enterobacteria colonizing animal guts, which also do not possess the cytochrome aa3 oxidase.

The phylogenetic tree of the protein subunits of cytochrome bo3 oxidase of AAB matches that inferred using 70 proteins from the core genome (supplementary table S1, Supplementary Material online, and fig. 1), indicating that bo3 oxidase evolution followed the differentiation of AAB species from a common ancestor. On the other hand, the phylogenetic tree of the cytochrome bd oxidases has a topology that is different from the phylogenomics inferred from core genes (fig. 2). In the bd oxidase tree, Saccharibacter branches with Acetobacter species rather than with Gluconobacter (fig. 2) suggesting that lateral gene transfer of bd oxidase genes might have occurred along the evolution of AAB.

In sum, although AAB are usually described as strictly aerobic organisms thriving in normoxic environments, our results show that most of these organisms also possess ubiquinol oxidases that should allow their survival under micro-oxic conditions, such as those existing in the insect gut (Sudakaran et al. 2012). Moreover, phylogenetic comparisons show that these terminal oxidases were present in the common ancestor of AAB, thereby constituting an ancestral character. We thus propose that the capacity to thrive at low oxygen concentration conferred by ubiquinol oxidases has provided AAB organisms with a constitutive propensity for thriving in micro-oxic environments including the insect gut, an environment with ample variation in its oxygen levels (Sudakaran et al. 2012). The deep branching of the AAB family contains pathogens such as Granulibacter bethesdensis (figs. 1 and 2) further supports that capacity to establish intimate associations with animal hosts is an ancestral trait in these bacteria. On the other hand, the association of AAB with phylogenetically diverse insect species (Crotti et al. 2010) can be considered rather recent, in view of the phylogenetic proximity of symbionts and free-living bacteria (Chouaia et al. 2010).

The analysis of the genomes presented here thus provides new clues indicating ancient pre-adaptation traits to symbiosis in AAB organisms that might have helped, and are still helping, establishing association with insects.

A cluster analysis carried on the ortholog gene groups that were not part of the core genes of the 16 AAB species showed that, in terms of gene acquisitions and losses, there was a coherence at the genus level: All of the members of a given
Fig. 1.—Comparison of species (AAB) (A) and operon (ubiquinol oxidase bo3) (B) in phylogenetic trees. The scientific names reported at the terminal nodes are those of the bacterial species. The tree of AAB (top) is based on the results of 70 concatenated protein (supplementary table S1, Supplementary Material online) phylogenetic analyses. Operon tree (bottom) was derived from the phylogeny inferred from the bo3 operon. The topology shown was obtained by the program RAxML using a partitioned ML model after reconstruction with 1,000 rapid bootstrap.
FIG. 2.—Comparison of species (AAB) (A) and operon (cytochrome oxidase bd) (B) in phylogenetic trees. The scientific names at the terminal nodes are those of the bacteria species. The tree of AAB (top) is based on the results of 70 concatenated protein phylogenetic analyses. Operon tree (bottom) was derived from the phylogeny inferred from the bd operon. The tree topology and other details were as given in figure 1.
Genus clustered together, except for G. diazotrophicus and A. aceti (fig. 3). However, when only orthologs present in at least 50% of the genomes are considered, the clustering resulting from the analysis of shared genes is congruent to the phylogeny based on the 70 coding sequences (CDS), including the positioning of G. diazotrophicus and A. aceti (figs. 1A and 4). In other words, phenetic analysis based on gene presence/absence produced a tree comparable to that generated by phylogenetics. This result supports the robustness of the phylogenomics here presented for AAB. It is noteworthy that the phylogenomic tree based on 70 CDS was not congruent with 16S rRNA-based phylogeny (supplementary fig. S1, Supplementary Material online).

Electron Chain Transport and Symbiotic Traits

The analysis of the phylogeny of the cytochrome oxidase operons bo$_3$ and bd showed that both of them were ancestral. The analysis showed also that cytochrome oxidase bo$_3$ had an evolutionary history similar to that of the AAB genomes. These results suggest that these two operons may have played a role in the symbiotic potential of the AAB.

In order to investigate the possible implication of other proteins of the electron transport chain in the pre-adaptation of AAB to a symbiotic life, a further cluster analysis was carried on the different orthologs involved in the electron transport chain that were present in the different genomes. This analysis showed that the pattern of gain, loss, and duplication of these genes was coherent and allowed to identify two groups (fig. 5), although there was no correlation between the presence of certain groups of orthologs and the ability to establish symbiosis. The two groups that were identified were the same that emerged from the phylogenomic study. The first group was formed by members of the Acetobacter and Gluconacetobacter genera, whereas the second group was formed by members of the Gluconobacter genus in addition to Asaia and Saccharibacter.

Materials and Methods

Strains

Asaia platycodi strain SF2.1 was isolated from An. stephensi (Favia et al. 2007). Saccharibacter sp. strain AM169 was isolated from an adult gut of Ap. mellifera using the pre-enrichment medium ABEM (2.0% D-sorbitol, 0.5% peptone, 0.3% yeast extract pH 3.5; Favia et al. 2007) supplemented with 100 μg ml$^{-1}$ of cycloheximide, followed by a plating on CaCO$_3$-containing plates (1.0% D-glucose, 1.0% glycerol, 1.0% ethanol, 1.0% peptone, 0.5% yeast extract, 0.7% CaCO$_3$, and 1.5% agar, pH 6.8). Saccharibacter sp. strain AM169 colony was selected based on the capability to clear CaCO$_3$. Both strains were characterized as aerobic, Gram-negative, and rod-shaped bacteria belonging to the family Acetobacteraceae.
Fig. 4.—Cluster analysis carried on the subset ortholog groups that were present in at least 50% of the genome. The analysis shows that the clustering of the different groups is congruent with the phylogenomic analysis carried on 70 CDS (fig. 1A).

Fig. 5.—Gene presence–absence analysis of the oxidative phosphorylation chain orthologs in the genomes of AAB. A hierarchical clustering tree (left) was inferred based on the Kulczynski dissimilarity matrix calculated on the presence–absence matrix of genes in the examined genomes. The heatmap to the right of the tree represents the values of the Kulczynski dissimilarity matrix.
Genome Sequencing, Assembly, and Annotation

The whole genome DNAs of *A. platycodi* SF2.1 and *Saccharibacter* sp. AM169 were purified using the DNeasy® Blood and Tissue kit (QIAGEN) and sequenced by Macrogen Korea institute. The genome sequence of *A. platycodi* SF2.1 was determined using a 3-kb paired-end library (~200 × 10⁶ reads, ~80 Mb) with the Genome Sequencer FLX system (Roche, Diagnostics, Branford, CT) and a 100-bp library (~28 × 10⁶ reads, ~3 Gb) with Genome AnalyzerIIx (Illumina, San Diego, CA). Raw data were assembled into 27 contigs—generated using Mira (version 3.4) (Chevreux et al. 1999); total coverage over the whole genome reached ~500-fold. The draft genome was 3,420,092 bp in length and contained 3,137 open reading frames (ORFs). The G+C content of the genome was 59.9%. The genome of *Saccharibacter* sp. AM169 was obtained from a tenth if a lane of Illumina Hiseq2000 platform generating 101-pb-long pair-end reads (~24 × 10⁶ reads, ~2.4 Gb). The nine contigs were generated using Velvet (version 1.2) (Zerbino and Birney 2008); total coverage over the whole genome reached ~1000-fold. The draft genome was 1,978,091 bp in length and contained 1,877 ORFs. The G+C content of the genome was 59.3% (table 1).

The functional annotation of the predicted genes was performed using the RAST server (Aziz et al. 2008) combined with KEGG database. The search for specific genes was carried out by local BLAST against the genomes of *G. oxydans* and *Gluconacetobacter diazotrophicus* using the KEGG database. The search for specific genes was carried out by local BLAST against the different genomes downloaded from the NCBI website using well-characterized and annotated genes. Confirmation or rectification of genes' annotation was obtained by additional DeltaBLAST analysis (http://blast.ncbi.nlm.nih.gov/Blast.cgi, last accessed April 8, 2014).

The result of this whole-genome project has been deposited at EMBL/GenBank database under the accession numbers CBXL010000001–CBXL0100000027 for *A. platycodi* and CBLY010000001–CBLY010000009 for *Saccharibacter* sp. The material described in this article corresponds to the first version of the submitted genomes.

### Phylogenomics and Phylogenetic Reconstruction of Specific Operons

For the phylogenetic reconstruction of the AAB, 14 available (table 2), complete or draft, genomes were downloaded from the NCBI database along with our two genomes. A standardized ORF calling using Prodigal (Hyatt et al. 2010) was performed on all the nucleotidic sequences and nontruncated proteins longer than 50 residues were kept for the following analysis. Orthologs present in a single copy in any given genome were then selected using OrthoMCL (Li et al. 2003).

and a custom script designed to keep only those matching with a single or no COG entry. The amino acid sequences of CDS belonging to each ortholog family were aligned using MUSCLE (Edgar 2004); the alignments were subsequently retro-transcribed to their respective nucleic acid sequences, which were checked for the probability of recombination and lateral gene transfer using the phi-test under the Phi-pack (Bruen et al. 2006). At the end of this screening, 70 proteins were kept for phylogenetic analysis (listed in supplementary table S1, Supplementary Material online). The alignment for the remaining CDS was Gblocked, keeping only the proteins that had <3 misaligned residues. For each of the aligned CDS, an evolutionary model was predicted using ProtTest (Darriba et al. 2011); then all the protein sequences were concatenated and their phylogenetic tree was constructed with RAxML (Stamatakis et al. 2005) using a partitioned Maximum Likelihood model that takes into account the evolutionary model predicted for each of the CDS. The phylogenetic trees were tested with 1,000 rapid bootstraps. The phylogenetic trees of the concatenated protein subunits of the cytochrome bo3 and bd oxidases were constructed with the same method. A phylogenetic tree based on 16S rRNA was also inferred (see supplementary material, Supplementary Material online).

Cluster Analysis on the Orthologs

The data obtained from OrthoMCL (5,488 ortholog groups) were transformed into a matrix reporting the presence of each ortholog group. The orthologs present in all of the genomes (i.e., core genome) were removed from the data set, leaving 4,575 ortholog groups, and a cluster analysis (Murtagh 1985) was carried out using R (cran.r-project.org, last accessed April 8, 2014). A second cluster analysis was carried out on a subset consisting only of the ortholog groups (1,167 ortholog groups) present in at least 50% of the genomes. The pattern of presence/absence was reconstructed also for the subset of genes involved in the oxidative phosphorylation chain. The oxidative phosphorylation chain genes (listed in supplementary table S2, Supplementary Material online) were identified on the basis of KEGG annotation of the Gluconacetobacter diazotrophicus PAI 5, G. oxydans H24, Ac. pasteurianus IFO 3283-01, and Granulibacter bethesdensis strain genomes; the relative presence/absence informations were retrieved from the OrthoMCL matrix generated above and organized in a new matrix. This new matrix was subjected to hierarchical clustering analysis using the Kulczynski distance index and the heat-map graphic representation was generated with R.

Supplementary Material

Supplementary methods, tables S1 and S2, and figure S1 are available at Genome Biology and Evolution online (http://www.gbe.oxfordjournals.org/).
