ABSTRACT
The research purposes were to analyze land use's effect on soil physical properties and measure several lands' soil quality index in the Bulili plateau. Its conducted on three types of land use consisted of a mixed plantation, maize plantation, and forest. Soil sampling at each type of land use was carried out at five different points so that in total, there were 15 locations for soil sampling. Soil samples were taken at a depth of 0-30 cm after removing the organic layer on the soil surface. Observation of soil physical properties, including clay content, bulk density, total porosity, saturated hydraulic conductivity, organic carbon, aggregate stability, and available soil water capacity, were used to design soil quality index models. Root depth was also observed. The results showed a significant effect of land-use change on all observed soil physical properties parameters. The soil quality index for mixed plantation, maize plantation, and forest belonged to the criteria of good (0.6474), quite poor (0.3486), and good (0.6590), respectively. Land-use change caused the soil's function to conserve biological activities to decline higher than the functions of soil water redistribution and filter - buffer.

Keywords: Critical land, Land use type, Model, Soil quality index, Palu watershed

1. INTRODUCTION
Damage to the ecosystem in the upstream Palu watershed area harmed the emergence of flood disasters, landslides, and reduced soil water supply in the last ten years. Natural disasters that had occurred for a long period had a real psychosocial impact on the community [1]. Land-use change was the main factor affecting the physical properties of the soil. Soil erosion and sedimentation significantly affected changes in carbon stocks, soil structure, and soil water flows [2,3]. Soil bulk density, pore space volume, aggregate stability, hydraulic conductivity, and soil water holding capacity were significantly affected by changes in forest land-use types to dry land agriculture [4,5].

The high dependence on soil water supply from the upstream Palu watershed caused water sources in the area to be preserved. Dryland management that considers soil-water conservation aspects needs to be designed to maintain water sources' sustainability in the area [6]. Conflict of interest in land use in the Palu watershed had led to severe land degradation [7]. To solve the complexity of problems in the land resource management system, an adaptive tool was needed. The availability of sufficient data was often the main obstacle for policy managers to formulate critical land management plans. Simplifying the system being studied into an adaptive model will make it easier for a planner to solve complex problems [8].

Previous research had developed a soil quality assessment model based on soil-climate parameters, carbon stocks, and soil pollution [9-12]. However, developing a suitable model to support critical land management in the upstream Palu watershed was still needed. Knowledge of soil physical properties affected by changes in land-use types was used as a parameter to design a model that suits the area's dryland management needs. The research objectives included: 1) determining the effect of land-use types on several soil physical properties, and 2) determining the soil quality index for mixed plantations, maize plantation, and forest land use type.
2. MATERIALS AND METHODS

2.1. Research Sites

The research was conducted in the Bulili plateau from January to June 2020. The area was located in the upper Palu watershed, Central Sulawesi, Indonesia. The land survey was carried out on three types of land use: 1) mixed plantation (Theobroma cacao L., Leucaena leucochepala, Artocarpus heterophyllus), 2) Maize plantation, and 3) forests (Aleurites moluccana, Palaquim sp., Aquilaria malaccensis).

The soil survey was conducted on three types of land use: 1) mixed plantation (Theobroma cacao L., Leucaena leucochepala, Artocarpus heterophyllus), 2) maize plantation, and 3) forests (Aleurites moluccana, Palaquim sp., Aquilaria malaccensis).

2.2. Sampling

Soil samples were taken from the soil surface layer (0 - 30 cm) to analyze soil physical properties in the laboratory. The collection of disturbed and undisturbed soil samples for each land use type was carried out at five different location points. Overall, this study consisted of 15 observation points.

Disturbed soil samples were air-dried at room temperature and sieved to pass a 2 mm diameter sieve. Some of the physical properties of the soil observed in the study included: soil texture (pipette method), total organic carbon (Walkley-Black), content weight (gravimetric). The total porosity of the soil was determined by the equation (1-ρb/ρp), where ρb represents bulk density and ρp represents particle density. The hydraulic conductivity of saturated soil (constant head permeameter), moisture content of field capacity, and permanent wilt point were determined by the gravimetric method (pressure plate apparatus at -33 kPa and -1.500 kPa). The available capacity was determined by calculating the difference between the field capacity’s water content and the permanent wilt point. The root depth was determined by drilling the ground in the field.

2.3. Research Analysis

The research data were analyzed using ANOVA, and if there was an effect of the treatment, the Duncan Multiple Range Test (α: 0.05) was carried out. To determine the correlation between the soil's physical properties that affected the aggregate stability and the available soil water capacity, correlation analysis and simple linear regression was carried out.

The soil quality index was determined based on a modification of the model developed by [13]. The score was calculated by comparing the observational data from the soil indicator and the assessment function. The scores ranged from 0 for bad conditions and 1 for good conditions. The scoring could be done through interpolation or simple linear regression equations according to the range of values or data obtained. The soil quality index was determined by multiplying the weight index with the indicator score [13] with the equation (1):

Table 1. Modified soil function, weights, and indicators for assessing soil quality index

| Soil Function          | Weight (1) | Soil Indicator                  | Weight (2) | Weight (3) | Weight Index | Upper Limit | Lower Limit |
|------------------------|------------|--------------------------------|------------|------------|--------------|-------------|-------------|
| Preserving Biological Activity | 0.4        | Rooting Medium                 | 0.5        |            |              | X1          | X2          |
|                        |            | Root Depth (cm)                | 0.60       | 0.12       | 138          | 55          | 0           |
|                        |            | Soil Bulk Density (g cm⁻³)     | 0.40       | 0.08       | 1.39         | 1.21        | 1           |

The results showed that changes in land use types significantly affected soil physical properties observed in the study. The differences in the effect of changes in land use types on soil physical properties were presented in Table 3 and Table 4.

Table 3 shows that the high clay content and low organic matter in the land use type of maize plantation had a low aggregate stability index. This was due to the formation of a massive soil structure. The wetting process and mechanical disturbances in soil with a texture loam - clayey loam and low organic matter cause soil aggregates to break down more easily [14,15]. The relationship between several soil physical properties and the aggregate stability index was presented in Figure 1.

Aggregate stability and soil water holding capacity were effective parameters for studying soil quality [16]. A strong relationship between the parameters of soil physical properties and the soil aggregate stability index and available soil water capacity could be used as a basis for thinking to develop a model [17]. The relationship between several soil physical properties and available soil water capacity was presented in Figure 2.

Clay content, bulk density, porosity, hydraulic conductivity, and soil organic carbon strongly correlated with the available soil water capacity (Figure 2). The soil quality assessment model's design uses soil physical properties parameters that strongly correlate to produce a robust model [18,19]. The use of soil erodibility index parameters as a standard for assessing soil quality could produce an adaptive model for critical land management planning [20,21].

The soil's function to conserve biological activity in the land use type of maize plantation was 131% and 114% lower, respectively, compared to the forest and mixed plantation (Table 5).

Shallow root depth could affect the storage capacity in the land use type of maize plantation. Lack of water during the flowering period could result in loss and failure of production. The minimum tillage treatment is a better option for farmers to improve soil aggregate stability and available capacity [22]. The land function for water redistribution in mixed plantation and forest land-use types was 41% and 39% higher, respectively, compared to maize plantation (Table 6). The increasing water movement rate on the soil surface due to soil tillage could lead to increased deposition of clay particles up to a depth of 45 cm [23].

The initial soil water content significantly influenced the compaction process in clay textured soils. Sandy soil density did not depend on the initial soil water content but was influenced by the initial soil bulk density. The

Table 2. Soil quality criteria

| No. | Soil Quality Index | Soil Quality Criteria |
|-----|-------------------|-----------------------|
| 1   | 0.00 – 0.10       | Poor                  |
| 2   | 0.10 – 0.19       | Slightly Poor         |
| 3   | 0.20 – 0.39       | Moderate              |
| 4   | 0.30 – 1.00       | Good                  |
| 5   | 1.00 – 1.50       | Very Good             |

3. RESULTS AND DISCUSSION

The results showed that changes in land use types significantly affected soil physical properties observed in the study. The differences in the effect of changes in land use types on soil physical properties were presented in Table 3 and Table 4.

Notes: RD = Root Depth, C = Clay, Si = Silt, S = Sand, BD = Bulk Density, TP = Total Porosity, HC = Hydraulic Conductivity, OC = Organic Carbon, ASI = Aggregate Stability Index, FC = Field Capacity, Soil Water Content = PWP = Permanent Wilting Point Soil Water Content, ASWC = Available Soil Water Capacity
increase in bulk density in clay soil caused an increase in the formation of micro pore spaces. Soil hydraulic conductivity decreases with increasing micropore space volume \[24\].

Organic carbon and available soil water capacity were parameters that play an important role in influencing soil as a filter and buffer. Changes in land use from forest to mixed plantation and maize plantation caused changes in the soil function index as filter and buffer by 4% and 108%, respectively (Table 7). Organic carbon and available soil water capacity had an important role in maintaining the soil's function as a filter and buffer. High soil organic carbon in forest and mixed plantation land uses caused the index of soil function as a filter and buffer higher than maize plantation. Intensive tillage practices could lead to the decreased organic carbon content in the land use type of maize plantation. Soil tillage had a strong influence on the decomposition of organic carbon at the soil surface. Soil organic carbon fell by up to 37% in intensive tillage treatments \[25, 26\]. On the other hand, organic carbon increases in the left undisturbed land in the long term \[27, 28\].

### Table 4. Different effects of changes in land use types on several soil physical properties

| Land Use Type       | Clay          | Bulk Density | Total Porosity | Hydraulic Conductivity | Carbon Organic | Aggregate Stability | Field Capacity Water Content | Available Soil Water Capacity |
|---------------------|---------------|--------------|----------------|------------------------|----------------|---------------------|-------------------------------|-----------------------------|
| Mixed Plantation    | 32.97\textsuperscript{a} | 1.24\textsuperscript{a} | 44.26\textsuperscript{b} | 3.31\textsuperscript{b} | 2.59\textsuperscript{b} | 59.6\textsuperscript{b} | 17.24\textsuperscript{b} | 13.12\textsuperscript{b} |
| Maize Plantation    | 46.87\textsuperscript{b} | 1.37\textsuperscript{b} | 39.75\textsuperscript{a} | 2.52\textsuperscript{a} | 1.90\textsuperscript{a} | 53.4\textsuperscript{a} | 16.04\textsuperscript{a} | 11.86\textsuperscript{a} |
| Forest              | 34.93\textsuperscript{a} | 1.25\textsuperscript{a} | 44.39\textsuperscript{b} | 3.35\textsuperscript{b} | 2.72\textsuperscript{b} | 59.2\textsuperscript{b} | 17.15\textsuperscript{b} | 13.00\textsuperscript{b} |

The numbers followed by different letters shown significant differences according to the Duncan multiple range test ($\alpha$: 0.05).

Figure 1 Relationship between clay content (a), soil bulk density (b), hydraulic conductivity saturated (c) organic carbon (d) and soil aggregate stability.
The change in land use from forest to mixed plantation did not cause a change in the soil quality index. On the other hand, land use for maize plantation had caused the soil quality index to drop by up to 89%. The soil quality criteria for maize plantation land-use types were quite poor (Table 8).

The burning of crop residues and plant litter was a major factor that causes the loss of organic carbon in agricultural land. Organic carbon stocks in the 12 years old cocoa land use type with an agroforestry pattern had not fully met conservation farming needs. Soil erosion in the cocoa land use type was still higher than tolerable soil erosion [29,30].

Soil physical properties that predominantly affected changes in soil quality could not be identified in this study. The development of further research related to soil erodibility would be very useful for developing a soil quality assessment model on degraded land [31,32].

**Figure 2** The relationship between clay (a), bulk density (b), total porosity (c) Saturated hydraulic conductivity, (d) organic carbon, (e) and available soil water capacity
4. CONCLUSION

Changes in land-use types from forest to maize plantation had a significant effect on soil physical properties. However, soil physical properties in mixed plantation land-use types were not significantly different from the forest. The soil quality index for forest land use, mixed plantation, and maize plantation were classified as good (0.6590), good (0.6474), and somewhat poor (0.3486), respectively.

Further research based on soil erodibility parameters would be very useful for developing critical land management models. The implication of this study's results was the formulation of an adaptive soil quality assessment model to develop a critical land management policy design in the Palu watershed.
