Abstract
In lacrimal system lacerations the canaliculi are involved in many of cases. Canalicular lacerations need urgent primary microsurgical repair. During surgery, it is extremely difficult to find the medial ostium of the canaliculi in severely damaged canalici cuts. In this instance, pigtail probe helps surgeon locate the medial portion of the cut canalici. In this study, a new technique has been presented for the complicated canalicular injuries. With this new technique the knot will stay in the nasal cavity unexposed, therefore the patients will be more comfortable during their recovery period.

Introduction
Silicon tube intubation during canalicular damage repair is a necessary procedure in order to obtain patent opening. It is an easy procedure in the case of smooth canalicular cuts. However, it is extremely difficult to locate the proximal end of the canalicular in complicated cuts [1-6]. In these situations, pigtail probe is very useful to find the medial end of the canalici and implantation of silicone tube. When medial segment is found and if it possible to reach to nasal cavity through this segment, monocalanicular tubes would be enough to complete intubation successfully. However, in severe damaged canalicular cuts, and in cases when it is impossible to reach canalici from medial segment, a silicone tube is attached to pigtail with prolen sutures and this pigtail probe is pulled through the secure canaliculi and withdrawn from the other punctum. Then, following repairment of cut, silicone tubes are tied in order to keep ties in the medial canthus. This tube is left about 3 to 6 months in order to complete recover of the canalici. However, the knot in the medial cantus poses ocular surface problems such as stinging and irritation of ocular surface.

From this point of view, a new technique is described which keeps silicone tube knot in the nasal cavity in order to prevent ocular surface damage.

Method

Lower canaliculi cuts
Upper punctum is dilated with a punctum dilatator. Pigtail probe is placed through the upper canaliculi and the medial portion of lower canaliculi is located. Silicon tube is inserted through lower punctum and is pulled through the lateral portion of the cut canaliculi. The probe of the silicone tube is removed and the tip of the tube is attached to pigtail probe with a 5/0 prolen suture (Figure 1). Pigtail probe is pulled through carefully and silicone is caught from the upper punctum. Silicone tube is deattached by a scissor from the pigtail probe (Figure 2). On the second stage, a new probe is attached which allows an access to the nasal cavity, to free the end of the silicone tube. Following enough dilatation of the punctum, this new probe goes through the upper canaliculi and it is pulled through the nose with an aid of nasal speculum (Figure 3). In this situation, a silicone tube intubation with one end in the lower punctum and the other end in the nasal cavity is accomplished (Figure 4). If bicanalicular intubation is wanted, third stage is performed. In this instance, the probe mentioned above is attached to the free end of the silicone tube on the lower punctum. This probe goes through upper punctum and is pulled through nasal cavity as mentioned above (Figure 5). In this example, both tubes are intubated and pulled through the nose. The free ends of the tubes are tied in the nasal cavity (Figure 6).

Upper canaliculi cuts
Lower punctum is dilated enough with a punctum dilatator. Pigtail probe goes through the lower canaliculi and the medial portion of the upper canaliculi is located. Silicone tube goes through upper punctum and is pulled through lateral portion of the cut canaliculi. The probe of the silicone tube is removed and the tip of the tube is attached to

**Figure 1.** Pigtail probe goes through the upper canaliculi and the medial portion of lower canaliculi is located. Silicone tube goes through lower punctum and pulled through lateral portion of the cut canaliculi. The probe of the silicone tube is removed and the tip of the tube is attached to pigtail probe with a 5/0 prolen suture.

Discussion

In lacrimal system lacerations the canaliculi are involved in 70% of cases [7]. The inferior canaliculus is the most commonly affected but both canaliculi can be damaged by injuries [8]. Lacrimal system lacerations may occur the results of sharp or blunt trauma. Canalicular lacerations need urgent primary microsurgical repair with silicone intubation. During of procedure, it is extremely difficult to find the medial ostium of the canaliculi in severely damaged canaliculi cuts [1-6]. We herein presented a surgical approach of retrograde approach by using an endoscope to identify the medial ends of canalicular laceration [9]. In these instances, pigtail probe helps surgeon locate the medial portion of the cut canaliculi. However, in several damaged cases, silicone tube is pulled through the healthy punctum with the aid of the pigtail probe. The free ends of the silicone tube are tied in the medial canthus but this knot significantly irritates ocular surface. In this article, we presented a new technique for the complicated canalicular injuries. With this new technique the knot will stay unexposed in the nasal cavity and the patients will be symptom free during their recovery period.
