Data deposition: The genome assembly, annotation data of this project have been deposited at the European Nucleotide Archive under accession number FJUY01000001-FJUY01000078. The RNA-seq of the project have been deposited at the NCBI Gene Expression Omnibus under GEO Series accession number GSE109135.

Abstract

Ramularia leaf spot has recently emerged as a major threat to barley production world-wide, causing 25% yield loss in many barley growing regions. Here, we provide a new reference genome of the causal agent, the Dothideomycete Ramularia collo-cygni. The assembly of 32 Mb consists of 78 scaffolds. We used RNA-seq to identify 11,622 genes of which 1,303 and 282 are coding for predicted secreted proteins and putative effectors respectively.

The pathogen separated from its nearest sequenced relative, Zymoseptoria tritici/C24 27 Ma. We calculated the divergence of the two species on protein level and see remarkably high synonymous and nonsynonymous divergence. Unlike in many other plant pathogens, the comparisons of transposable elements and gene distributions, show a very homogeneous genome for R. collo-cygni.

We see no evidence for higher selective pressure on putative effectors or other secreted proteins and repetitive sequences are spread evenly across the scaffolds. These findings could be associated to the predominantly endophytic life-style of the pathogen. We hypothesize that R. collo-cygni only recently became pathogenic and that therefore its genome does not yet show the typical pathogen characteristics. Because of its high scaffold length and improved CDS annotations, our new reference sequence provides a valuable resource for the community for future comparative genomics and population genetics studies.

Key words: fungi, phytopathology, genome, dothideomycetes, barley pathogen.

Introduction

The filamentous ascomycete fungus Ramularia collo-cygni was first described in 1893 as Ophiocladium hordei (Cavara 1893). It is the biotic agent of ramularia leaf spot (RLS) (Oxley and Havis 2004), a disease typically occurring late in the growing season on the upper canopy (Salamati and Reitan 2006). Since the mid-1980s it has become the major pathogen in many barley growing regions worldwide and quickly developed resistance to major fungicides (Matusinsky et al. 2011; Havis et al. 2015; Piotrowska et al. 2017). It can now be detected in barley samples worldwide (Havis et al. 2015) and in infected fields it is estimated to cause losses around 25% of the yield potential through a significant decrease of kernel size and quality (Harvey 2002).
A draft genome assembly of *R. collo-cygni* strain DK05, isolated in Denmark, had been published previously (McGrann et al. 2016). Like its closest sequenced relative *Zymoseptoria tritici*, *R. collo-cygni* has few plant cell wall degrading enzyme genes and a large number of gene clusters associated with secondary metabolite production. These findings are thought to be linked to the relatively long period of asymptomatic growth of both pathogens inside the host.

We present an independent draft genome of a strain isolated in southern Uruguay. The significantly increased scaffold size enabled several analyses related to genome architecture. Moreover, our improved annotation allows for more reliable identification of genes that are under positive selection and may be involved in pathogenicity.

**Materials and Methods**

**Genome Assembly and Annotation**

A detailed description of the genome sequencing strategy, assembly and annotation can be found in the supplementary files. In short: sequencing was done by Eurofins Genomics GmbH, Germany, using a short distance library (SD) (insert size, 500 bp, paired-end sequencing 2 × 150 bp) and a LJD (jumping distance 8-kb, paired-end sequencing 2 × 300 bp). RNA-seq was performed using TruSeq Rapid PE Cluster (PE-402-4001) and the TruSeq Rapid SBS (FC-402-4001) Kits.

The assembly was performed by ALLPATHS-LG (Gnerre et al. 2011) using ~100-fold SD and ~30-fold LJD coverage. Gene models were generated by 1) FgeneSH (Salamov and Solovyev 2000), 2) GeneMark-ES (Ter-Hovanissyan et al. 2008), and 3) AUGUSTUS (Stanke et al. 2011). RNA-seq transcripts were assembled using Trinity (Grabherr et al. 2011). Gene models were visualized in GBrowse (Donlin 2009), allowing manual validation of coding sequences. The best fitting model per locus was selected manually and gene structures were adjusted by splitting or fusing of gene models or redefining exon–intron boundaries if necessary.

The protein coding genes were analyzed and functionally annotated using the PEDANT system (Walter et al. 2009). We combined SecretomeP1.1 (Bendtsen, Jensen, et al. 2004), SignalP3 (Bendtsen, Nielsen, et al. 2004), and SignalP4.0 (Petersen et al. 2011) with TargetP1.1 (Emanuelsson et al. 2007), TMHMM2.0 (Krogh et al. 2001) to predict secreted proteins. For effector prediction, this set was submitted to EffectorP 2.0 (Sper Schneider et al. 2016). Repetitive elements were identified using the RepeatModeler pipeline (Smith 2013), which is based on RepeatScout (Price et al. 2005).

Further Analyses

Orthologous genes for 10 main housekeeping genes were selected from the proteomes of *Urug2*, 15 closely related species and three more distal species that are available from the FunyBASE (Marthey et al. 2008). We performed a ClustalW pairwise alignment and multiple alignment with standard parameters for the combined proteins of all species (*An, Aspergillus nidulans; Bc, Botrytis cinerea; Bg, B. graminis; Cb, Cercospora beticola; Cg, Colletotrichum graminicola; Ds, Dothistroma septosporum; Fg, Fusarium graminearum; Pf, Fusarium fujikuroi; Mf, Pseudocercosporella herpotrichoides; Mo, Magnaportha grisea; Pi, Piriformospora indica; Pr, P. triticicrepentis; Pt, P. teres f. teres; Rc, R. collo-cygni; Sn, P. nodorum; Sm, Sphaerulina musiva; Um, Ustalago maydis; Zt, Z. tritici; Outgroup, Laccaria bicolor*) using Mega X (Kumar et al. 2018). Dating of the *Zt–Rc* split was done using the RelTime method (Tamura et al. 2012), where Lb was used as an outgroup and the data were calibrated using the Um to An split (Taylor and Berbee 2006).

Orthologous genes to all single copy genes were identified in the *Zt* proteome (BLASTP e-value: 10−10), only reciprocal matches were used and globally aligned using t-coffee (default parameters) (supplementary table S5, Supplementary Material online). Amino acids were replaced by codons from the CDS sequence using pal2nal (Suyama et al. 2006). The di/VdS ratios were calculated with PAML (Yang and Nielsen 2000). Intergenic distances and TE distances were calculated using bedtools (closest) (Quinlan and Hall 2010). Genome alignments between the assembly of *Urug2* and that of DK05 were inferred using nucmer (with –maxmatch, otherwise default options) from the MUMmer package (version 3.23) and alignments that span >1 kb and are >90% identical in sequence were plotted using Gnuplot.

**Results**

**Genome Properties**

Combining short distance with long jumping distance libraries (LJDs), we obtained a ~32-Mb assembly of *R. collo-cygni* isolate *Urug2*, in 78 scaffolds with an N50 scaffold size of 2.1 Mb, compared with 576 scaffolds and an N50 of 0.21 in the previous DK05 assembly (table 1). Dot plot analysis comparing both *Urug2* to DK05, shows strong linearity suggesting little to no overassembly (supplementary fig. S1, Supplementary Material online). To bolster gene annotations, we sequenced mRNA isolated from *R. collo-cygni* grown under six axenic conditions to generate a diverse set of transcripts. Using these data mapped to the genome, the annotation was manually corrected gene by gene, yielding a more reliable set of gene models (example shown in supplementary fig. S2, Supplementary Material online). The curated *R. collo-cygni* genome contains 11,622 protein coding genes of which 11,125 show expression evidence (95.7%, supplementary table S1, Supplementary Material online). We predicted 1,303 secreted proteins ranging in length from 41 to

---

3244  *Genome Biol. Evol.* 10(12):3243–3249 doi:10.1093/gbe/evy240  Advance Access publication October 29, 2018

Stam et al.
3,256 amino-acids, representing around 9% of the predicted proteome, among which 282 effector candidates genes (putative effectors) (2%) (supplementary table S2, Supplementary Material online). These numbers are an increase over the previous R. collo-cygni assembly that contained 1,053 putative secreted proteins and 150 effector candidates.

The general genome features are comparable to other Dothideomycete plant pathogens with available genome sequences (Parastagonospora nodorum SN15, Hane et al. 2007; Syme et al. 2013, Pyrenophora tritic-repentis BFP-ToxAC, Manning et al. 2013, Pyrenophora teres f. teres 0-1, Wyatt et al. 2018, and Z. tritici IPO323, Goodwin et al. 2011; table 1). We estimated genome completeness using BUSCO (version 3.0.1). 96.8% of the genes were detected as complete and single-copy in the R. collo-cygni Urug2 assembly. This exceeds the completeness of R. collo-cygni DK05 (93.9%) and Z. tritici IPO323 (92.5%) and is similar to P. teres f. teres 0-1 (supplementary table S3, Supplementary Material online).

Gene Expression Analysis

We saw similar levels of gene expression in all six tested media, with a slightly larger fraction of genes expressed in Barley Straw Agar (BSA), a host-mimicking agar medium compared with neutral or pH-adjusted media (supplementary table S1, fig. S3A, Supplementary Material online). We found a larger number of differentially expressed genes (DEGs) (>4-fold change) in BSA (supplementary fig. S3B, Supplementary Material online). We expected that gene expression in BSA most closely resembles infection of the plant. Indeed, we found that the fraction of putative secreted proteins and effector candidates is two times higher in the BSA differentially expressed genes than in the genome as a whole (resp. 22% and 5%).

Table 1

| Isolate              | Ramularia collo-cygni | Ramularia collo-cygni | Phaeosphaeria nodorum | Pyrenophora tritic-repentis | Pyrenophora teres-teres | Zymoseptoria tritici |

| Number of predicted effectors* | 282                  | 150                   | 625                    | 382                       | 337                     | 380                |

Note.—Genome statistics were taken from the respective publications for each organism. The number of putative secreted proteins and effector candidates was recalculated for each species except DK05, using our newest pipeline.

* DK05 gene/protein models were not publicly available.

Strong Divergence from Z. tritici

We reconstructed a phylogenetic tree of R. collo-cygni, with 15 more closely and three more distantly related species (fig. 1) and confirm that R. collo-cygni falls within the Mycosphaerellaceae clade of the Dothideomycete class. Ramularia collo-cygni (Rc) diverged from the closest sequence relative, Z. tritici (Zt) 27 Ma. To gain insight in the differentiation of R. collo-cygni from Z. tritici, we calculated the ratio of non-synonymous over synonymous substitutions (dN/dS) (fig. 2). The very high dS indicate that these two species have significantly diverged since the split. When comparing the dN/dS between the two species for the putative secreted proteins and putative effectors, we find that the putative secreted proteins show a slightly higher dN/dS ratio than nonsecreted proteins (Dunn’s multiple comparisons Kruskal–Wallis test, P = 4.7 x 10^{-16}). For the effectors this difference is not significant (P = 0.16). Effectors and secreted proteins also show no significant differences (P = 0.2). In terms of absolute values and outliers, there are no putative effectors that stand out. Similar results can be observed when comparing differentially expressed genes on BSA. As mentioned above, these genes are hypothesized to be important for virulence on barley, yet there are no significant differences in dN/dS between these BSA up- or down regulated genes and nonDEGs or between up or down regulated genes in general (fig. 3C, Dunn’s multiple comparisons Kruskal–Wallis test, P > 0.01).

The R. collo-cygni Genome Is Relatively Repeat Poor and Homogeneous

We compared the content of noncoding sequences and repeat sequences like DNA transposons and other transposable elements (TEs) (supplementary table S4, Supplementary Material online). In terms of repeat sequence content, R. collo-cygni is placed at the low end of the spectrum amongst...
Dothideomycetes. Only 6% of the genome consists of TEs, whereas in P. tritici-repentis, P. teres f. teres, and Z. tritici this is 21%, 38%, and 17%, respectively. Next, we compared the distance of predicted genes to its nearest repeat sequence as well as the general intergenic distance. Close association of genes to TEs and large intergenic distance for regions with high effector content are features of a so-called “two-speed-genome” and often associated with accelerated evolution (Raffaele and Kamoun 2012). Figure 3A shows that intergenic distances are not differently distributed between putative effectors genes or other genes and the mean values for the difference to the nearest TE for putative effectors and putative secreted proteins are not significantly different from the distances for not secreted proteins (effector: 304: 1,739 bp, secreted: 305: 2,486 bp, other: 306: 1,924 bp).
5′: 1,646 bp, secreted 3′: 1,659 bp, 5′: 1,715 bp, nonsecreted: 3′: 1724, 5′: 1727) (Dunn’s multiple comparisons Kruskal–Wallis test, \( P > 0.1 \)). Lastly, we also do not find a significant correlation between the number of TEs per kb/scaffold or the number of effectors or secreted proteins (Spearman rho, \( P > 0.01 \), fig. 3C; supplementary fig. S4).

**Discussion**

A first draft genome of *R. collo-cygni* (isolate DK05) had been available since 2016. The data suggested a genetic composition that might at least partially explain the lifestyle of *R. collo-cygni*, which is characterized by a long endophytic phase throughout the life cycle of the host and an intense parasitic phase during crop senescence (McGrann et al. 2016). We generated an independent draft genome and annotation for another isolate (Urug2) to get better insights in the *R. collo-cygni* genome structure. We assembled the 32-Mb genome into only 78 scaffolds with 11,622 high confidence genes. Our expression data greatly helped with gene annotations and provide interesting insights in genes expressed under different axenic conditions. This will help researchers to verify target gene candidates for functional studies, yet to truly understand gene expression during the infection process, additional RNA-Seq from infected plant tissue will be required.
Our sequencing approach allowed for comparative studies and confirmed that unlike many other pathogens R. collo-cygni did not undergo any genome expansions since it diverged from its nearest sequenced sister species 27 Ma. Unlike what can be seen between certain fungal and oomycete species, where the numbers of genes in some effector families differ up to an order of magnitude (Stam et al. 2013) the numbers of putative effectors in R. collo-cygni are comparable with that of related fungi.

We performed pairwise comparisons of the coding sequences of R. collo-cygni and the related wheat pathogen Z. tritici. The dN/dS ratio has a simple and intuitive interpretation of selection pressure, but comes with limitations, especially when dS is high (Kryazhimskiy and Plotkin 2008). However, our analyses provide interesting insights. Contrary to the phenomenon observed in a large number of other plant pathogens, we see little evidence for accelerated evolution of secreted proteins, putative effectors or genes that are likely differentially expressed during infection, between R. collo-cygni and Z. tritici. This is in stark contrast to for example Colletotrichum species, where high dN/dS of effectors was associated with the switch from endophytic to parasitic lifestyle (Hacquard et al. 2016). This however, leaves the possibility that this switch is still ongoing in R. collo-cygni. The species can also infect other graminaceous hosts, but with less severe symptoms it often appears endophytic (Kaczmarek et al. 2017).

From Z. tritici, R. collo-cygni’s nearest sequenced relative, we know that rapid pathogen evolution can often be associated with high repeat content of the genome (Poppe et al. 2015), or close physical association of TEs with putative effector genes, which results in a so-called “two-speed” genome architecture. Also for other Dothideomycetes like P. nodorum (Richards et al. 2018) and P. teres f. teres (Wyatt et al. 2018) this two speed genome is evident. In P. tritic-repentis TE content has even be directly associated with the pathogenicity of the strains (Manning et al. 2013). In R. collo-cygni repeat content is low and secreted proteins or putative effectors are not closely associated with TEs. Other examples of typical “one-speed-genome” pathogen is the biotrophic barley pathogen Blumeria graminis (Frantzsekkas et al. 2018). However, that species is relatively unrelated and has a very different lifestyle. Comparing the mechanisms that drive evolution of pathogenicity in these two diverse one-speed-genome barley pathogens will be particularly interesting. Also, additional investigation is TEs and the relatedness to host, host specificity and aggressiveness as a pathogen in R. collo-cygni and other Dothideomycetes will likely teach us more on how this diverse class of cereal pathogens arose and became successful. Our new reference genome and improved annotation provides a starting point for doing so.
