Abstract. As an alternative to dark energy it has been suggested that we may be at the center of an inhomogeneous isotropic universe described by a Lemaitre-Tolman-Bondi (LTB) solution of Einstein’s field equations. In order to test such an hypothesis we calculate the low redshift expansion of the luminosity distance $D_L(z)$ and the redshift spherical shell mass density $mn(z)$ for a central observer in a LTB space without cosmological constant and show how they cannot fit the observations implied by a $\Lambda CDM$ model if the conditions to avoid a weak central singularity are imposed, i.e. if the matter distribution is smooth everywhere. Our conclusions are valid for any value of the cosmological constant, not only for $\Omega_\Lambda > 1/3$ as implied by previous proofs that $q_{0}^{app}$ has to be positive in a smooth LTB space, based on considering only the luminosity distance.

The observational signatures of smooth LTB matter dominated models are fundamentally different from the ones of $\Lambda CDM$ models not only because it is not possible to reproduce a negative apparent central deceleration $q_{0}^{app}$, but because of deeper differences in their space-time geometry which make impossible solve the inversion problem when more than one observable is considered, and emerge at any redshift, not only for $z = 0$.

Keywords: dark energy theory, supernovas, redshift surveys, galaxy surveys

ArXiv ePrint: 0912.2866
1 Introduction

High redshift luminosity distance measurements [28, 37–41] and the WMAP measurement [42, 44] of cosmic microwave background (CMB) interpreted in the context of standard FLRW cosmological models have strongly disfavored a matter dominated universe, and strongly supported a dominant dark energy component, giving rise to a positive cosmological acceleration. As an alternative to dark energy, it has been proposed [13, 14] that we may be at the center of an inhomogeneous isotropic universe described by a Lemaitre-Tolman-Bondi (LTB) solution of Einstein’s field equations, where spatial averaging over one expanding and one contracting region is producing a positive averaged acceleration $a_D$. Another more general approach to map luminosity distance as a function of redshift $D_L(z)$ to LTB models has been recently proposed [31, 32], showing that an inversion method can be applied successfully to reproduce the observed $D_L(z)$. Interesting analysis of observational data in inhomogeneous models without dark energy is given for example in [15, 19]. In [33] it is also given some direct evidence from the analysis of observational data that the smoothness of the large scale inhomogeneity profile is important to allow to distinguish these models from $\Lambda CDM$, which is consistent with our conclusion that smooth LTB models can be distinguished from $\Lambda CDM$, at least in principle, without any ambiguity.

The main point is that the luminosity distance is in general sensitive to the geometry of the space through which photons are propagating along null geodesics, and therefore arranging appropriately the geometry of a given cosmological model it is possible to reproduce a given $D_L(z)$. For FLRW models this corresponds to the determination of $\Omega_\Lambda$ and $\Omega_m$ and for LTB models it allows to determine the functions $E(r), M(r), t_b(r)$.

Another observable which could be used to constrain LTB models is the redshift spherical shell mass $mn(z)$ [2], recently calculated [4] for a central observer up to the fifth order. This quantity is the product of the number of sources $n(z)$ times their mass $m(z)$, and can be related to observations by using the following relation with the total redshift rest mass...
$M_T(z)$, defined as the total rest mass of all the sources with redshift equal or less than $z$:

$$M_T(z) = \int_{0}^{z} 4\pi mn(z')dz',$$  \hspace{1cm} (1.1)  

$$4\pi mn(z) = \frac{M_T(z)}{dz}.$$  \hspace{1cm} (1.2)  

Once an actual accurate estimation of $mn(z)$ based on observational data from galaxy surveys will be available, this quantity could be used to distinguish without ambiguity between smooth LTB and $\Lambda$CDM models, but an even better candidate as a discriminating observable would be the redshift spherical energy $E_{RSS}$ introduced in [46], which has the additional advantage of avoiding source evolution effects. $E_{RSS}$ is in fact obtained by integrating $mn(z)$ over varying redshift intervals $\Delta Z(z)$

$$E_{RSS}(z) = \int_{z}^{z+\Delta Z(z)} 4\pi mn(z')dz',$$  \hspace{1cm} (1.3)  

$$t(z) - t(z + \Delta Z(z)) = \Delta t,$$  \hspace{1cm} (1.4)  

which preserve the constant time interval $\Delta t$. By choosing $\Delta t$ to be sufficiently smaller than the time scale over which astrophysical evolution is important, we can avoid the effects of the source evolution.

In this paper we calculate the low redshift expansion of $mn(z)$ and $D_L(z)$ for flat $\Lambda$CDM and matter dominated smooth LTB models. We then show how, if the conditions to avoid a central weak singularity are imposed, it is impossible to mimick dark energy with a LTB model without cosmological constant for both these observables, giving a general proof of the impossibility to give a local solution of the inversion problem for a smooth LTB model. This central singularity is rather mild, and is associated to linear terms in the radial coordinate $r$ for the energy density which lead to a divergence of its second derivative, so non smooth LTB models could still be viable cosmological models. It can be shown in fact that the inversion problem [7] can be solved if the smoothness conditions we are imposing are relaxed. This implies that the numerical solutions of the inversion problem which have been recently proposed [11, 21] must contain such a weak central singularity.

Our proof of the impossibility of the local solution of the inversion problem is general, since we don’t use any special ansatz for the functions defining LTB models, and it does not depend on the particular value of $\Omega_\Lambda$. In this regard we obtain a much stronger result than the one already well known fact [16] that $q_0^{app}$ cannot be negative for a smooth LTB model. In fact even if $q_0^{app} > 0$, which for a flat $\Lambda$CDM would imply $\Omega_\Lambda < \frac{1}{3}$, it would still be impossible to mimick the cosmological constant for both $mn(z)$ and $D_L(z)$. This means that the difference between a smooth spherically symmetric pressureless matter dominated Universe and a homogeneous Universe with a cosmological constant goes beyond the sign of $q_0^{app}$, and corresponds to distinctive observational features not only at $z = 0$.

2 Lemaitre-Tolman-Bondi (LTB) solution

Lemaitre-Tolman-Bondi solution can be written as [8–10]

$$ds^2 = -dt^2 + \frac{(R_r)^2}{1+2E} dr^2 + R^2d\Omega^2,$$  \hspace{1cm} (2.1)
where $R$ is a function of the time coordinate $t$ and the radial coordinate $r$, $R = R(t, r)$, $E$ is an arbitrary function of $r$, $E = E(r)$ and $R_{,r} = \partial R/\partial r$.

Einstein’s equations give

$$
\left( \frac{\dot{R}}{R} \right)^2 = \frac{2E(r)}{R^2} + \frac{2M(r)}{R^3}, \tag{2.2}
$$

$$
\rho(t, r) = \frac{2M_r}{R^2R_{,r}}, \tag{2.3}
$$

with $M = M(r)$ being an arbitrary function of $r$ and the dot denoting the partial derivative with respect to $t$, $\dot{R} = \partial R(t, r)/\partial t$. The solution of eq. (2.2) can be expressed parametrically in terms of a time variable $\tau = \int t' dt'/R(t', r)$ as

$$
Y(\tau, r) = \frac{M(r)}{-2E(r)} \left[ 1 - \cos \left( \sqrt{-2E(r)} \tau \right) \right], \tag{2.4}
$$

$$
t(\tau, r) = \frac{M(r)}{-2E(r)} \left[ \tau - \frac{1}{\sqrt{-2E(r)}} \sin \left( \sqrt{-2E(r)} \tau \right) \right] + t_b(r), \tag{2.5}
$$

where $Y$ has been introduced to make clear the distinction between the two functions $R(t, r)$ and $Y(\tau, r)$ which are trivially related by

$$
R(t(\tau, r)) = Y(\tau, r), \tag{2.6}
$$

and $t_b(r)$ is another arbitrary function of $r$, called the bang function, which corresponds to the fact that big-bang/crunches can happen at different times. This inhomogeneity of the location of the singularities is one of the origins of the possible causal separation between the central observer and the spatially averaged region for models with positive $a_D$. This solution is also valid of positive $E$, by trivial analytical continuation.

We introduce the variables

$$
A(t, r) = \frac{R(t, r)}{r}, \quad k(r) = \frac{-2E(r)}{r^2}, \quad \rho_0(r) = \frac{6M(r)}{r^3}, \tag{2.7}
$$

so that eq. (2.1) and the Einstein equations (2.2) and (2.3) are written in a form similar to those for FLRW models,

$$
ds^2 = -dt^2 + A^2 \left[ \left( 1 + \frac{A_{,r}r}{A} \right)^2 \frac{dr^2}{1 - k(r)r^2} + r^2d\Omega_2^2 \right], \tag{2.8}
$$

$$
\left( \frac{\dot{A}}{A} \right)^2 = -\frac{k(r)}{A^2} + \frac{\rho_0(r)}{3A^3}, \tag{2.9}
$$

$$
\rho(t, r) = \frac{(\rho_0 r^3)_{,r}}{3A^2r^2(2r)^{,r}}. \tag{2.10}
$$

The solution of eqs. (2.4) and (2.5) can now be written as

$$
a(\eta, r) = \frac{\rho_0(r)}{6k(r)} \left[ 1 - \cos \left( \sqrt{k(r)} \eta \right) \right], \tag{2.11}
$$

$$
t(\eta, r) = \frac{\rho_0(r)}{6k(r)} \left[ \eta - \frac{1}{\sqrt{k(r)}} \sin \left( \sqrt{k(r)} \eta \right) \right] + t_b(r), \tag{2.12}
$$

\[ \text{(3)} \]
where $\eta \equiv \tau r = \int^t dt'/A(t',r)$ and $A(t(\eta, r), r) = a(\eta, r)$.

In the rest of paper we will use this last set of equations. Furthermore, without loss of generality, we may set the function $\rho_0(r)$ to be a constant, $\rho_0(r) = \rho_0 = \text{constant}$, corresponding to the choice of coordinates in which $M(r) \propto r^3$, and we will call this, following [13], the FLRW gauge.

We need three functions to define a LTB solution, but because of the invariance under general coordinate transformations, only two of them are really independent. This implies that two observables are in principle sufficient to solve the inversion problem of mapping observations to a specific LTB model, for example the luminosity distance $D_L(z)$ and the redshift spherical shell mass $m(z)n(z) = mn(z)$. As observed by [21], there has been sometime some confusion about the general type of LTB models which could be used to explain cosmological observations, so it is important to stress that without restricting the attention on models with homogeneous big bang, a void is not necessary to explain both $D_L(z)$ and $m(z)n(z) = mn(z)$ without the cosmological constant, but we will prove that this is only possible for LTB models that contain a weak central singularity.

3 Geodesic equations

We will adopt the same method developed in [18] to find the null geodesic equation in the coordinates $(\eta, t)$, but here instead of integrating numerically the differential equations we will find a local expansion of the solution around $z = 0$ corresponding to the point $(t_0, 0) \equiv (\eta_0, t)$, where $t_0 = t(\eta_0, r)$. We will also provide more details about the geodesic equation derivation which were presented in [18] in a rather concise way. We will indeed slightly change notation to emphasize the fully analytical r.h.s. of the equations obtained in terms of $(\eta, t)$, on the contrary of previous versions of the light geodesic equations which require some numerical calculation of $R(t, r)$ from the Einstein’s equation (2.2). For this reason this formulation is particularly suitable for the derivation of analytical results.

The luminosity distance for a central observer in a LTB space as a function of the redshift is expressed as

$$D_L(z) = (1 + z)^2 R(t(z), r(z)) = (1 + z)^2 r(z)a(\eta(z), r(z)),$$

where $(t(z), r(z))$ or $(\eta(z), r(z))$ is the solution of the radial geodesic equation as a function of the redshift. The past-directed radial null geodesic is given by

$$\frac{dT(r)}{dr} = f(T(r), r); \quad f(t, r) = \frac{-R_r(t, r)}{\sqrt{1 + 2E(r)}},$$

where $T(r)$ is the time coordinate along the null radial geodesic as a function of the the coordinate $r$. From the implicit solution, we can write

$$T(r) = t(U(r), r), \quad \frac{dT(r)}{dr} = \frac{\partial t}{\partial \eta} \frac{dU(r)}{dr} + \frac{\partial t}{\partial r},$$

where $U(r)$ is the $\eta$ coordinate along the null radial geodesic as a function of the the coordinate $r$. Since it is easier to write down the geodesic equation in the coordinate $(t, r)$ we will start
from there \[12\]:

\[
\frac{dr}{dz} = \frac{\sqrt{1 + 2E(r(z))}}{(1 + z)R'[r(z), t(z)]}, \tag{3.5}
\]

\[
\frac{dt}{dz} = -\frac{R'[r(z), t(r)]}{(1 + z)R'[r(z), t(z)]},
\]

where the \( \prime \) denotes the derivative respect to \( r \) and the dot \( \dot{\cdot} \) the derivative respect to \( t \). These equations are derived from the definition of redshift and by following the evolution of a short time interval along the null geodesic \( T(r) \).

The problem is that there is no exact analytical solution for \( R(t, r) \), so the r.h.s. of this equations cannot be evaluated analytically but requires to find a numerical solution for \( R \) first \[30\], and then to integrate numerically the differential equation, which is a quite inconvenient and difficult numerical procedure. Alternatively a local expansion for \( R(t, r) \) around \((t_0, 0)\), corresponding to the central observer, could be derived and used in eq. (3.6), but being an expansion will loose accuracy as the redshift increases.

For this reason it is useful for many numerical and analytical applications to write the geodesic equations for the coordinates \((\eta, r)\),

\[
\frac{d\eta}{dz} = \frac{\partial_t t(\eta, r) - F(\eta, r)}{(1 + z)\partial_\eta F(\eta, r)} = p(\eta, r), \tag{3.6}
\]

\[
\frac{dr}{dz} = -\frac{a(\eta, r)}{(1 + z)\partial_\eta F(\eta, r)} = q(\eta, r), \tag{3.7}
\]

\[
F(\eta, r) = -\frac{1}{\sqrt{1 - k(r)r^2}} [\partial_r (a(\eta, r)r) + \partial_\eta (a(\eta, r)r)\partial_r \eta], \tag{3.8}
\]

where \( \eta = U(r(z)) \) and \( F(\eta, r) = f(t(\eta, r), r) \). It is important to observe that the functions \( p, q, F \) have an explicit analytical form which can be obtained from \( a(\eta, r) \) and \( t(\eta, r) \) as shown below. The derivation of the implicit solution \( a(\eta, r) \) is based on the use of the conformal time variable \( \eta \), which by construction satisfies the relation

\[
\frac{\partial \eta(\tau, r)}{\partial \tau} = a^{-1}. \tag{3.9}
\]

This means

\[
t(\eta, r) = t_b(r) + \int_0^\eta a(\eta', r)d\eta', \tag{3.10}
\]

\[
dt = a(\eta, r)d\eta + \left( \int_0^\eta \frac{\partial a(\eta', r)}{\partial r}d\eta' + t_b'(r) \right) dr. \tag{3.11}
\]

In order to use the analytical solution we need to find an analytical expression for \( F \) and \( F_{\eta} \). This can always be done by using

\[
\frac{\partial}{\partial t} = a^{-1} \frac{\partial}{\partial \eta}, \tag{3.12}
\]

\[
\partial_r t(\eta, r) = \frac{\rho_0 k'(r)}{12k(r)^{5/2}} \left[ 3 \sin \left( \eta \sqrt{k(r)} \right) - \eta \left( 2 + \cos \left( \eta \sqrt{k(r)} \right) \sqrt{k(r)} \right) \right] + t_b'(r), \tag{3.13}
\]

\[
\partial_r \eta = -a(\eta, r)^{-1} \partial_r t \tag{3.14}
\]

In this way the coefficients of equations (3.6) and (3.7) are fully analytical, which is a significant improvement over previous approaches.
Calculating $D_L(z)$ and $mn(z)$

Expanding the r.h.s. of the geodesics equation we can easily integrate the corresponding polynomial $q(z), p(z)$, to get $r(z)$ and $\eta(z)$. It can be shown that in order to obtain $D_L(z)$ to the third order and $mn(z)$ the fourth we need to expand $r(z)$ to the third order and $\eta(z)$ to the second. In the FLRW gauge in order to avoid a weak central singularity \[16\] we need the following expansion for $k(r)$ and $t_b(r)$:

\[
k(r) = k_0 + k_2 r^2, \quad (4.1)
\]
\[
t_b(r) = t_b^0 + t_{b1} r^2, \quad (4.2)
\]

which are based on the fact that taking only even powers the functions are analytical everywhere, including the center.

Here we will not give the formulae in terms of $\eta_0$ and trigonometric functions, since they are rather complicated and not relevant to the scope of this paper, but rather introduce the following quantities:

\[
a_0 = \frac{\tan(\sqrt{k_0}\eta_0)^2 \rho_0}{3k_0 \tan(\sqrt{k_0}\eta_0)^2 + 3k_0}, \quad (4.3)
\]
\[
H_0 = \frac{3k_0^{3/2} \left( \tan(\sqrt{k_0}\eta_0)^2 + 1 \right)}{\tan(\sqrt{k_0}\eta_0)^3 \rho_0}, \quad (4.4)
\]
\[
q_0 = \frac{1}{2} \left( \tan \left( \frac{\sqrt{k_0}\eta_0}{2} \right)^2 + 1 \right), \quad (4.5)
\]

where we have used

\[
a_0 = a(\eta_0, 0), \quad (4.6)
\]
\[
H_0 = \frac{\dot{a}(t_0, 0)}{a(t_0, 0)}, \quad (4.7)
\]
\[
q_0 = -\frac{\ddot{a}(t_0, 0) \dot{a}(t_0, 0)}{\dot{a}(t_0, 0)^2}. \quad (4.8)
\]

The derivative respect to $t$ is denoted with a dot, and is calculated using the analytical solution $a(\eta, r)$ and the derivative respect to $\eta$:

\[
\dot{a} = \partial_t a = \partial_\eta a a^{-1}. \quad (4.9)
\]

It is important to observe that in general, without imposing the smoothness conditions, we have eight independent parameters

\[
\rho_0, \eta_0, t_{b0}^1, t_{b1}^1, t_{b2}^1, k_0, k_1, k_2. \quad (4.10)
\]

The conformal time coordinate of the central observer $\eta_0$ is not really independent, in the sense that it has to be consistent with the age of the universe, which, if we assume the inhomogeneities to be only local, should be approximatively the same as the one estimated in $\Lambda CDM$ models. We get six constraints from the expansion of $mn(z)$ and $D_L(z)$ respectively to fourth an third order, so in principle without imposing the smoothness conditions $t_{b1}^1 =
$k_1 = 0$ we should be able to solve the inversion problem of locally mapping a LTB model to
any given ΛCDM model, even taking into account the fact that, as we will show later, $mn(z)$
and $D_L(z)$ don’t depend on $t_0^b$. It is also clear that a simple preliminary argument based on
counting the number of independent parameters imply that the inversion problem cannot be
solved for a smooth model, i.e. if $t_1^b = k_1 = 0$, since we have six constraints and only five
dependent parameters. We will show this more explicitly in the rest of the paper.

After re-expressing the results in terms of $H_0, q_0, a_0$ we get

\[
\eta(z) = \eta_0 + \eta_1 z + \eta_2 z^2 + \ldots
\]

\[
r(z) = r_1 z + r_2 z^2 + r_3 z^3 + \ldots
\]

\[
\eta_1 = -\frac{1}{a_0 H_0},
\]

\[
\eta_2 = \frac{\sqrt{2 q_0 - 1} \left( a_0^4 H_0^4 (4 q_0^3 - 3 q_0 + 1) - 2 a_0^2 H_0^2 (1 - 2 q_0) t_0^b - 3 k_2 \right) + 2 k_2 (q_0 + 1) \arctan \sqrt{2 q_0 - 1}}{2 a_0^2 H_0^2 (2 q_0 - 1)^{3/2}},
\]

\[
r_1 = \frac{1}{a_0 H_0},
\]

\[
r_2 = -\frac{q_0 + 1}{2 a_0 H_0},
\]

\[
r_3 = \frac{1}{2 a_0^3 H_0^3 (2 q_0 - 1)^3} \left[ (2 q_0 - 1) \left( a_0^4 H_0^4 (1 - 2 q_0)^2 (q_0^2 + 1) - 2 a_0^2 H_0^2 (1 - 2 q_0)^2 q_0 t_2^b - 5 k_2 q_0 + k_2 \right) + 6 k_2 \sqrt{2 q_0 - 1} \right].
\]

It is important to observe that this formulae are valid, by analytical continuation, also for
negative $k_0$, i.e. also for $q_0 < 1/2$.

We can then calculate the luminosity distance:

\[
D_L(z) = (1 + z) r(z) a(\eta(z), r(z)) = D_L^1 z + D_L^2 z^2 + D_L^3 z^3 + \ldots
\]

\[
D_L^1 = \frac{1}{H_0},
\]

\[
D_L^2 = \frac{1 - q_0}{2 H_0},
\]

\[
D_L^3 = \frac{1}{2 a_0^3 H_0^3 (2 q_0 - 1)^{3/2}} \left[ \sqrt{2 q_0 - 1} \left( a_0^4 H_0^4 (1 - 2 q_0)^2 (q_0 - 1) q_0 - 2 a_0^2 H_0^2 (1 - 2 q_0)^2 (q_0 - 1) q_0 t_2^b - 9 k_2 q_0 \right) + 6 k_2 q_0 (q_0 + 1) \arctan \sqrt{2 q_0 - 1} \right].
\]

From the definition of $mn(z)$ and the equation for the energy density we can write

\[
4 \pi m(z) dz = \rho d^3 V = \frac{8 \pi M'}{\sqrt{1 - k(r)r^2}} dr,
\]

from which by using $dr = (dr/dz) dz$ we get

\[
mn(z) = \frac{2 M'(r(z)) dr(z)}{\sqrt{1 - k(r(z)) r(z)^2}} = \frac{\rho_0 r(z)^2 dr(z)}{\sqrt{1 - k(r(z)) r(z)^2}}.
\]

where in the last equation we have used the FLRW gauge condition $M(r) = \rho_0 r^3/6$, which
allows to calculate $mn(z)$ directly from $r(z)$. 

- 7 -
We finally get:

\[ mn(z) = mn_2 z^2 + mn_3 z^3 + mn_4 z^4 + \ldots \quad (4.21) \]

\[ mn_2 = \frac{6q_0}{H_0}, \quad (4.22) \]

\[ mn_3 = -\frac{12q_0(q_0 + 1)}{H_0}, \quad (4.23) \]

\[ mn_4 = \frac{3q_0}{2a_0^4 H_0^3 (2q_0 - 1)^3} \left[ (2q_0 - 1)(a_0^3 H_0^2 (1 - 2q_0)^2 (15q_0^2 + 14q_0 + 13) + \right. \]

\[ \left. -20a_0^2 H_0^2 (1 - 2q_0)^2 q_0 t_2 + 10k_2(1 - 5q_0) + 60k_2 \sqrt{2q_0 - 1} q_0^3 \arctan \sqrt{2q_0 - 1} \right]. \quad (4.24) \]

As it can be seen the effects of large-scale inhomogeneities show only from the fourth order, and while also the fifth order has been calculated [4], we don’t report it here since we don’t need it.

5 Relation with apparent observables

In this section we will briefly show the relation of the results obtained so far with apparent observables, which are defined as:

\[ H^{\text{app}}(z) = \left[ \frac{d}{dz} \left( \frac{D_L(z)}{1 + z} \right) \right]^{-1}, \quad (5.1) \]

\[ Q^{\text{app}}(z) = \frac{d}{dz} \left( \frac{D_L(z)}{1 + z} \right) = H^{-1}(z), \quad (5.2) \]

\[ q^{\text{app}}(z) = -1 - \frac{\ln(Q(z))}{\ln(1 + z)}. \quad (5.3) \]

By apparent here we mean that they are obtained using the relations expressed in eq. (5.1)–(5.3), which are true only in a flat FLRW space, but assuming that the observed luminosity distance used in these formulas correspond to a LTB model. As it could be expected on the basis of simple continuity arguments, for smooth LTB models the central values of the apparent observables coincide with their dynamical definitions from eq. (4.3)–(4.5):

\[ H_0 = \frac{\dot{a}(t_0, 0)}{a(t_0, 0)} = H^{\text{app}}(0) = H^{\text{app}}_0, \quad (5.4) \]

\[ q_0 = -\frac{\dot{a}(t_0, 0) \ddot{a}(t_0, 0)}{\dot{a}(t_0, 0)^2} = q^{\text{app}}(0) = q^{\text{app}}_0. \quad (5.5) \]

While it is worth mentioning this relation in order to better understand the physical meaning of the quantities we have introduced, it is important to observe that eq. (4.3)–(4.5) can be just considered a convenient and natural re-definition of the parameters of the problem based, and that we don’t need neither use anywhere in our calculations the concept of apparent \( q^{\text{app}}(z) \) and \( H^{\text{app}}(z) \) introduced above.

We can also observe that our results are consistent with the fact that \( q^{\text{app}}_0 \) must be positive in absence of a weak central singularity, since the value calculated in eq. (4.5) is always positive for any value of \( q_0 \) or \( k_0 \). It can be shown that equations (5.4)–(5.5) are not satisfied for not smooth models [7], which explains why in that case the inversion problem can be solved, since in those models \( q^{\text{app}}_0 \) can be negative.
6 Calculating $D_L(z)$ and $m n(z)$ for $\Lambda CDM$ models

The metric of a $\Lambda CDM$ model is the FLRW metric, a special case of LTB solution, where:

$$\rho_0(r) = \rho_0,$$  
(6.1)

$$k(r) = 0,$$  
(6.2)

$$t_b(r) = 0.$$  
(6.3)

In this section we will calculate independently the expansion of the luminosity distance and the redshift spherical shell mass for the case of a flat $\Lambda CDM$. We will also use these formulas to check the results given in the previous section, since in absence of cosmological constant and large-scale inhomogeneities they should coincide.

One of the Einstein equation can be expressed as:

$$H(z) = \frac{\Omega_m \left( \frac{a_0}{a} \right)^3}{\Omega_m + \Omega_\Lambda} = \frac{H_0}{\Omega_m (1 + z)^3 + \Omega_\Lambda}.$$  
(6.4)

We can then calculate the luminosity distance using the following relation, which is only valid assuming flatness:

$$D_L(z) = (1 + z) \int_0^z \frac{dz'}{H(z')} = D_L^1 + D_L^2 z^2 + D_L^3 z^3 + \ldots$$  
(6.5)

from which we can get:

$$D_L^1 = \frac{1}{H_0},$$  
(6.6)

$$D_L^2 = \frac{4\Omega_\Lambda + \Omega_M}{4H_0},$$  
(6.7)

$$D_L^3 = \frac{-10\Omega_\Lambda \Omega_M - \Omega_M^2}{8H_0}.$$  
(6.8)

It is convenient to re-express the above coefficient in terms of the two observables $H_0, q_0$

$$D_L^1 = \frac{1}{H_0},$$  
(6.9)

$$D_L^1 = \frac{1 - q_0}{2H_0},$$  
(6.10)

$$D_L^1 = \frac{3q_0^2 + q_0 - 2}{6H_0}.$$  
(6.11)

where we have used the following relations

$$\Omega_L + \Omega_M = 1,$$  
(6.12)

$$\Omega_M = \frac{2q_0 + 2}{3}.$$  
(6.13)

For calculating $m n(z)$ we first need $r(z)$, which can be obtained from the radial null geodesic equation which in this case takes the simplified form

$$\frac{dr}{dz} = \frac{1}{(1 + z)a} = \frac{1}{a_0 H},$$  
(6.14)
which can be easily integrated to give
\begin{equation}
    r(z) = \frac{1}{a_0} \int_0^z \frac{dz'}{H(z')} = \frac{z}{a_0 H_0} - \frac{(q_0 + 1)z^2}{2a_0 H_0} + \frac{3q_0^2 + 4q_0 + 1}{6a_0 H_0} z^3 + O(z^4).  \tag{6.15}
\end{equation}
We can now calculate \( mn(z) \)
\begin{equation}
    \rho_0 = 3a_0^2 \Omega_M H_0^2, \tag{6.17}
\end{equation}
\begin{equation}
    mn(z) = mn_2 z^2 + mn_3 z^3 + mn_4 = \frac{\rho_0 r(z)^2}{\sqrt{1 - k(r(z))r(z)^2}} \frac{dr(z)}{dz} \tag{6.18}
\end{equation}
\begin{equation}
    = \frac{2(q_0 + 1)z^2}{H_0} - \frac{4(q_0 + 1)^2 z^3}{H_0} + \frac{5(q_0 + 1)^2(9q_0 + 5)z^4}{6H_0} + O(z^5).  \tag{6.19}
\end{equation}
We can check the consistency between these formulae and the one derived in the case of LTB without cosmological constant by setting:
\begin{align}
    k_2 &= l_2^b = 0,  \tag{6.20} \\
    q_0 &= 1/2,   \tag{6.21}
\end{align}
which corresponds to the case in which \( \Omega_M = 1 \).

It is important to mention that \( a_0, q_0, H_0 \) defined in this section are in general different from the ones defined in the previous section for LTB models but for simplicity of notation we have used the same symbols. In the next section, where we will study the inversion problem, we will instead need to clearly distinguish between them and for that reason we will introduce \( a_0^\Lambda, q_0^\Lambda, H_0^\Lambda \) to indicate the ones corresponding to a \( \Lambda \)CDM model.

### 7 The inversion problem cannot be solved

In this section we will denote with an upper script \( \Lambda \) all the relevant quantities referred to a \( \Lambda \)CDM model, including the coefficients of the redshift expansion for \( D_L(z) \) and \( mn(z) \). In order to solve the inversion problem we need to solve the following system of six equations:
\begin{align}
    D_i^\Lambda &= D_i \quad 1 \leq i \leq 3,  \tag{7.1} \\
    mn_j^\Lambda &= mn_j \quad 2 \leq j \leq 4.  \tag{7.2}
\end{align}
It is evident that the first and second order term of the luminosity distance expansion imply that
\begin{align}
    q_0 &= q_0^\Lambda,  \tag{7.3} \\
    H_0 &= H_0^\Lambda.  \tag{7.4}
\end{align}
If we try match the second and third order term of \( mn(z) \) instead we get:
\begin{align}
    q_0 &= q_0^\Lambda,  \tag{7.5} \\
    H_0 &= \frac{(3H_0^\Lambda q_0^\Lambda)}{(1 + q_0^\Lambda)}.  \tag{7.6}
\end{align}
There is clearly no common solution unless $q_0 = \frac{1}{2}$, which corresponds exactly to set to zero the cosmological constant. This proof is general, since it does not depend on the particular value of $\Omega_\Lambda$, as long as it is non zero.

This is a stronger result than the one already well known fact that $q_{0}^{\text{app}}$ cannot be negative for a smooth LTB model. In fact even if $q_{0}^{\text{app}} > 0$, which for a flat $\Lambda CDM$ would imply $\Omega_\Lambda < \frac{1}{3}$, it would still be impossible to mimic the cosmological constant for both $m n(z)$ and $D_L(z)$. Smooth LTB models are in fact fundamentally different from $\Lambda CDM$ models, and the sign of $q_0^{\text{app}}$ is not the only important observational feature to focus on, but we should rather consider the full observational implications at various redshift, since quantities like $mn(z)$ encode much more information about the underlying space-time geometry than simply $q_{0}^{\text{app}}$. If we had relaxed the condition $\ell^b_1 = k_1 = 0$ the inversion problem could be solved, but we will study this in a separate future work [7], where we will also try to better understand the nature of the weak singularity occurring in this case.

8 Conclusion

We have we calculated the low redshift expansion of the luminosity distance $D_L(z)$ and the redshift spherical shell mass density $mn(z)$ for a central observer in a LTB space without cosmological constant showing how they cannot fit the observations implied by a $\Lambda CDM$ model if the conditions to avoid a weak central singularity are imposed, i.e. if the matter distribution is smooth everywhere. Our conclusions are valid for any value of the cosmological constant, not only for $\Omega_\Lambda > 1/3$ as implied by previous proofs that $q_{0}^{\text{app}}$ has to be positive in a smooth LTB space, based on considering only the luminosity distance. The observational signatures of smooth LTB matter dominated models are fundamentally different from the ones of $\Lambda CDM$ models not only because it is not possible to reproduce a negative apparent central deceleration $q_{0}^{\text{app}}$, but because of deeper differences in their space-time geometry which make impossible to solve the inversion problem when more than one observable is considered, and emerge at any redshift, not only for $z = 0$.

In the future it will be interesting to extend our investigation to the case of off-center observers and, as proposed in [5, 6], to study the effects of large-scale inhomogeneities in presence of a cosmological constant, or even of a more general type of dark energy. It would be for example interesting to estimate how the cosmological constant value or the effective equation of state of dark energy could be affected by large-scale inhomogeneities.

This problems will be addressed in future separate works.

Acknowledgments

I thank A. Starobinsky and M. Sasaki for useful comments and discussions, and J. Yokoyama for the for the hospitality at RESCUE. This work is supported by MEXT Grant-in-Aid for the global COE program at Kyoto University, “The Next Generation of Physics, Spun from Universality and Emergence”.
