rates of nulliparous (empty and unpi-
gmented abdomens) (9) adult midges 
observed when suction light traps 
(Onderstepoort Veterinary Institute, 
Onderstepoort, South Africa) were 
used on cattle farms during April– 
May 2007 (4).

We identified a breeding site for 
the primary BT virus vector in a cowshed 
in northern Europe (10). Vectors feed 
on blood, overwinter inside cowsheds 
(1), lay eggs, and larvae develop under 
such conditions. These observations 
could explain the persistence of BTV 
from year to year despite fairly harsh 
winters.

Hygienic measures on farms 
could reduce midge populations and 
improve efficacy of vaccination cam-
paigns against BT in Europe. We 
strongly recommend that such inte-
grated control strategies be evaluated. 
Removal of residual animal feed and 
feces on farms and of material from si-
tated control strategies be evalu-
ated. However, their success 
will depend on active participation by 
farmers.

Two Lineages of Dengue Virus Type 2, Brazil

To the Editor: Dengue viruses (DENVs) belong to the genus Flavivirus (family Flaviviridae) and exist as 
4 antigenic types, serotypes 1–4, each with well-defined genotypes. Dengue virus is associated with clinical mani-
festations that range from asymptomatic infections and relatively mild disease (classic dengue fever) to more 
severe forms of dengue hemorrhagic fever and dengue shock syndrome. Dengue has become one of the most 
serious vector-borne diseases in humans. The World Health Organization estimates that 2.5 billion persons live 
dengue-endemic areas and >50 million are infected annually (1).

In 1986, dengue virus type 1 (DENV-1) caused an outbreak in the 
state of Rio de Janeiro and has since 
become a public health concern and 
threat in Brazil. In 1990, DENV-2 
was reported in the state of Rio de 
Janeiro, where the first severe forms 
of dengue hemorrhagic fever and fatal 
cases of dengue shock syndrome were 
documented. The disease gradually 
spread to other regions of the country 
(3). In 2002, DENV-3 caused the most 
severe dengue outbreak in the country 
and sporadic outbreaks continued to 
be documented through 2005 (4).

Since 1990, two additional epidem-
ic events caused by DENV-2 have oc-
curred (1998 and 2007–2008) in Bra-
Ziel. A severe DENV-2 epidemic in 
the state of Rio de Janeiro began in 
2007 and continued in 2008; a total of 
255,818 cases and 252 deaths were re-
ported (5). This epidemic prompted us 
to investigate the genetic relatedness of 
DENV-2 for all of these epidemics. 
DENV-2 isolates from these 
epidemic periods were subjected to 
sequencing and comparison. Gross 
sequences of DENV-2 isolates from 
all epidemic periods grouped with 
sequences from DENV-2 American/
Asian genotype; this finding was expected because this genotype is circulating in the Americas (6,7). Sequences of DENV-2 isolates from the 1998 epidemic grouped with sequences of DENV-2 isolates from the 1990 epidemic (data not shown) suggesting that viruses circulating during these 2 epidemic periods belong to the same lineage of the DENV-2 strain originally found in the state of Rio de Janeiro. However, sequences of DENV-2 isolates from 2007/2008 epidemics grouped separately and distinctly from the 1990 and 1998 DENV-2 isolates and represented a monophyletic group in the phylogenetic tree with bootstraps of 98% (Figure). This result shows a temporal circulation of genetically different viruses in Rio de Janeiro that could be a result of local evolution of DENV-2 since its introduction in 1990, or even an introduction of a new lineage of DENV-2 in the region.

A study conducted by Aquino et al. (7) showed that Paraguayan DENV-2 strains could be grouped as 2 distinct variants within the American/Asian genotype, thus further supporting that the introduction of new DENV-2 variants may likely associate with the shift of dominant serotypes from DENV-3 to DENV-2 in 2005 and might have caused an outbreak of DENV-2. Our results are consistent with this scenario because was a shift of a dominant serotype from DENV-3 to DENV-2 that was observed in 2008 in Rio de Janeiro. However, other factors, such as immunity level to DENV-3 and DENV-2, could explain the shift of dominant serotype besides the circulation of a new viral variant.

Because the dengue outbreaks of 2007 and 2008 were the most severe of the dengue infections in Brazil in terms of number of cases and deaths, this genetically distinct DENV-2 could have contributed to this pathogenic profile. Additionally, these samples came from disperse locations in Rio de Janeiro and we do not believe that there is a clustering issue in our sampling. However, again, other factors must be considered as contributors to this scenario because of the intrinsic properties of this distinct virus, host susceptibility, and secondary cases of infection.

In addition, detailed examination of amino acid sequences of Brazilian DENV-2 strains isolated in 1998 and

Figure. Neighbor-joining phylogenetic tree of 68 complete envelope (E) gene sequences of dengue virus type 2 (DENV-2). Only bootstrap values >80% are shown. DENV-2 sequences obtained from 21 patients infected during the 1990, 1998, and 2007–2008 epidemics were isolated from acute-phase cases. Sequences of the E gene were compared with DENV-2 sequences of American/Asian genotype deposited in GenBank (www.ncbi.nlm.nih.gov). Strains of Asian genotype I served as the outgroup. All sequences were aligned by using ClustalX (www.ebi.ac.uk/clustalw), and phylogenetic analysis was performed by using MEGA 4.0 (www.megasoftware.net), according to the Tamura-Nei model. The reliability of the inferred phylogenetic tree was estimated by the bootstrap method, with 1,000 replications. Horizontal branch lengths are drawn to scale, and the tree was rooted by using Asian genotype I as the outgroup. Scale bar represents percentage of genetic distance. Black circles represent sequences generated in this study and sequences from Rio de Janeiro from 1998 and 2007–2008. The names of DENV-2 isolates from the 1990 epidemic grouped with sequences of Brazilian DENV-2 strains isolated in 1998 and
2008 showed 6 aa substitutions in the envelope gene: V129I, L131Q, I170T, and V707I. Our results support the notion that aa positions at 129 and 131 in the envelope gene are critical genetic markers for phylogenetic classification of DENV-2 (7–9).

Notably, residue 131 in the envelope gene is located within a pH-dependent hinge region at the interface between domains I and II of the envelope protein. Mutations at this region may affect the pH threshold of fusion and the process of conformational changes (10).

Our results suggest the circulation of genetically different DENV-2 in Brazil and that these viruses may have a role in severity of dengue diseases. These findings can help to further understand the complex dynamic pathogenic profile of dengue viruses and their circulation in dengue-endemic regions.

Yersinia Species Isolated from Bats, Germany

To the Editor: Bats are distributed worldwide and are among the most diverse and species-rich mammals on earth. They exist in a large variety of distinct ecologic niches. Many bat species roost near humans, which is of particular interest for research on bat-to-human transmission of potential zoonotic pathogens. Moreover, migratory bats could act as long-distance vectors for several infectious agents. In recent decades, scientific interest in chiropteran species has markedly increased because bats are known hosts to zoonotic agents, such as henipaviruses, Ebola virus, and severe acute respiratory syndrome (SARS)–like corona viruses (1,2). However, investigations regarding bacterial pathogens with potential for mutual transmission between bats and humans are sparse. The effect of bacterial agents on individual bats is largely unknown and has been neglected in most studies published to date (3).

We conducted a broad study during 2006–2008 on diseases and causes of death in bats among 16 species found in Germany. Two hundred deceased bats, collected in different geographic regions in Germany (southern Bavaria, eastern Lower Saxony, eastern Brandenburg, and Berlin greater metropolitan area), were subjected to necropsy and investigated by using routine histopathologic and bacteriologic methods. During necropsy, instruments were dipped in 70% ethanol and moved into a Bunsen burner flame after every incision to prevent any cross-contamination. For bacteriologic examination, tissue samples were treated accordingly to prevent environmental contamination. A freshly cut tissue surface was plated onto Columbia agar (5% sheep blood; Oxoid, Wesel, Germany), Gassner agar (Oxoid), and MacCo-
