Abstract
This paper is concerned with the numerical solution of nonlinear ill-posed operator equations involving convex constraints. We study a Newton-type method which consists in applying linear Tikhonov regularization with convex constraints to the Newton equations in each iteration step. Convergence of this iterative regularization method is analyzed if both the operator and the right-hand side are given with errors and all error levels tend to zero. Our study has been motivated by the joint estimation of object and phase in 4Pi microscopy, which leads to a semi-blind deconvolution problem with nonnegativity constraints. The performance of the proposed algorithm is illustrated both for simulated and for three-dimensional experimental data. (Some figures may appear in colour only in the online journal)

1. Introduction
In this paper, we present and analyze a Newton-type regularization method for nonlinear ill-posed operator equations with convex constraints. More specifically, let $\mathcal{X}$ and $\mathcal{Y}$ be Hilbert spaces, $\mathcal{C} \subset \mathcal{X}$ a nonempty, closed convex set, and $F: \mathcal{C} \to \mathcal{Y}$ a ‘forward’ operator, which we assume to be Gateaux differentiable. We consider the inverse problem of reconstructing $x^\dagger$ in the operator equation

$$F(x^\dagger) = g, \quad x^\dagger \in \mathcal{C} \quad (1.1)$$

if only noisy versions of both $F$ and $g$ are given. Moreover, we aim to prove convergence of such reconstructions as the noise levels tend to zero.

An inverse problem for which it is particularly important to properly incorporate a convex constraint into the inversion scheme arises in a confocal fluorescence microscopy technique (cf [19]) called 4Pi microscopy. This technique was suggested and developed by Hell et al.
Figure 1. The top line shows the psf of a 4Pi microscope modeled by (1.4) for relative phases $\varphi = 0$, $\frac{\pi}{2}$, $\pi$ on the plane containing the optical axis, which is indicated by the white arrow. The bottom line shows the more accurate model (3.1).

[11, 12] and allows for a substantial enhancement of resolution using interference of two laser beams in the microscopic focus and/or interference of fluorescence photons on the detector. In standard confocal microscopy, the relation between the unknown fluorescent marker density $f \in L^2(\mathbb{R}^3)$ of the specimen and the measured intensity $g$ is given by a convolution with a point spread function (psf) $h \in L^1(\mathbb{R}^3)$, which is often modeled as a Gaussian function:

$$g(x) = \int h(x - y)f(y)\,dy.$$  

(1.2)

The width of $h$ is typically much larger along the so-called optical axis (which we assume to be the $x_3$-axis) than in directions perpendicular to the optical axis. For an overview on the extensive literature on deconvolution methods for problems of the form (1.2), we refer to [4].

4Pi microscopy allows an increase of resolution along the optical axis by a factor of 3–7 using interference of coherent photons through two opposing objective lenses. Here the psf is no longer spatially invariant in general, but depends on the relative phase $\phi(x)$ of the interfering photons, which has to be recovered together with the fluorophore density $f$ in general since it depends on the refractive index of the specimen which is unknown. The imaging process can be modeled by an operator equation $F_{4\Pi}(f, \phi) = g$ with a forward operator of the form

$$F_{4\Pi}(f, \phi)(x) := \int p(y - x, \phi(x))f(y)\,dy.$$  

(1.3)

Note that $F$ is nonlinear in $\phi$ and that $f \mapsto F(f, \phi)$ is not a convolution operator in general. As a density, $f$ has to be nonnegative. Therefore, we have the convex constraint

$$(f, \phi) \in \mathcal{C} \quad \text{with} \quad \mathcal{C} := \{(f, \phi) : f \geq 0\}.$$

A simple frequently used model for the 4Pi-psf (cf, e.g., [1]) is given by

$$p(x, \varphi) \approx h(x)\cos^n \left(\frac{cx_3 + \varphi}{2}\right),$$  

(1.4)

where $h$ is the psf of the corresponding confocal microscope, and the cosine term represents the interference pattern for different types of 4Pi-microscopes corresponding to $n = 2, 4$, respectively (see figure 1). So far reconstruction of $f$ in commercially available 4Pi microscopes is done by standard deconvolution software assuming the relative phase function...
ϕ to be constant. Although spatial variations of ϕ can approximately be avoided experimentally in some situations, the assumption that ϕ is constant imposes severe limitations on the applicability and reliability of 4Pi microscopy. Therefore, it is of great interest to develop algorithms for the solution of the convexly constrained nonlinear inverse problem to recover both the object function f and the relative phase function ϕ from the data g.

To this end, we propose and analyze the following constrained version of the iteratively regularized Gauss–Newton method (IRGNM). We assume that both the right-hand side g in the operator equation \( (1.1) \) and the operator \( F \) are only given approximately with errors by \( g_δ \) and \( F_δ \), respectively. Error bounds will be specified in the next section. Given some initial guess \( x_0 \in C \), we consider the iteration

\[
x_{n+1} = \text{argmin}_{x \in C} [\|F_δ'[x_n](x - x_n) + F_δ(x_n) - g_δ\|^2 + \alpha_n\|x - x_0\|^2], \quad (1.5a)
\]

\[\alpha_n = 0, 1, 2, \ldots, \]

with a sequence of regularization parameters \( \alpha_n \) satisfying

\[
1 \leq \frac{\alpha_n}{\alpha_{n+1}} \leq r, \quad \lim_{n \to \infty} \alpha_n = 0, \quad \alpha_n > 0 \quad \text{for some } r > 1 \text{ and for all } n \in \mathbb{N}_0. \quad (1.5b)
\]

In the unconstrained case \( C = \mathcal{X} \), this reduces to the IRGNM as suggested in the original paper by Bakushinskii [2]. For \( C \neq \mathcal{X} \), a quadratic minimization problem with convex constraint has to be solved in each Newton step. In [2], convergence rates were shown for Hölder-type source conditions with the exponent \( \nu = 1 \). In [5, 14], order optimal convergence rates for more general Hölder type and logarithmic source conditions were proven. For numerous further references on the IRGNM and other iterative regularization methods, we refer to [3, 17]. More recently, Kaltenbacher and Hofmann [16] proved optimal convergence rates of the IRGNM in Banach spaces for general source conditions.

The plan of this paper is as follows: our main convergence result, theorem 2.1, is formulated and proved in section 2. Section 3 contains a more detailed discussion of 4Pi microscopy and the model \( (1.3) \), a comparison with other methods, and numerical results both for simulated and experimental data.

2. IRGNM with convex constraints

2.1. Formulation of the theorem

We assume that \( F, F_δ : \mathcal{C} \to \mathcal{Y} \) are both Gateaux differentiable with bounded derivatives \( F'[x], F_δ'[x] \) for all \( x \in \mathcal{C} \) and that the following error bounds hold:

\[
\|g - g_δ\| \leq \delta_g, \quad (2.1a)
\]
with noise levels $\delta_e, \delta_f, \delta_F \geq 0$.

Further we assume that a source condition of the form

$$x^\dagger = P_C(F'[x^\dagger] \omega + x_0) \quad \text{for some } \omega \in \mathcal{Y} \quad \text{with } \|\omega\| \leq \rho$$

is satisfied where $P_C: \mathcal{X} \to \mathcal{C}$ denotes the metric projection onto $\mathcal{C}$. The source condition (2.2a) corresponds to the one for linear constrained Tikhonov regularization that we assume in lemma 2.2, and since $R(T^*) = R((T^*T)^{1/2})$ for a bounded linear operator $T: \mathcal{X} \to \mathcal{Y}$ (cf [8, proposition 2.18]) it corresponds to a Hölder-type source condition with the exponent $v = \frac{1}{2}$. As the (2.2a) contains the projector $P_C$, it is less restrictive than in the unconstrained case $\mathcal{C} = \mathcal{X}$. In particular, $x^\dagger$ may not be smooth even if $F'[x^\dagger]$ is smoothing and $x_0$ is smooth.

Recently, it has been shown that (2.2a) is equivalent to a variational source condition [9].

If $F'[x^\dagger]$ is not injective, we further assume that $x^\dagger$ satisfies

$$x^\dagger = \arg\min_{x \in \mathcal{C} : F'[x^\dagger](x - x^\dagger) = 0} \|x - x^0\|.$$  

(2.2b)

Obviously, this condition is empty if $F'[x^\dagger]$ is injective. Moreover, if for any $\nu_0 \in N(F'[x^\dagger])$ there exists a differentiable curve $\nu: [0, \epsilon) \to \mathcal{C}$ with $\nu(0) = x^\dagger$, $\nu'(0) = \nu_0$ and $F(\nu(t)) = g$ for all $t$ (see e.g. [10] for a problem where this condition is satisfied), then it is easy to see that (2.2b) follows from $x^\dagger = \arg\min_{x \in \mathcal{C} : F'[x^\dagger](x - x^0)} \|x - x^0\|.$

As a nonlinearity condition on the operator $F_\delta$, we only need to assume that for some $\gamma > 0$ there exists a Lipschitz constant $L \geq 0$ such that

$$\|F_\delta[x] - F_\delta[x^\dagger]\| \leq L \|x - x^\dagger\| \quad \text{for all } x \in \mathcal{C} \quad \text{with } \|x - x^\dagger\| \leq \gamma.$$  

(2.3)

We can now formulate our main convergence theorem.

**Theorem 2.1.** Assuming that (1.1) and (2.1)–(2.3) are satisfied with $\rho$ sufficiently small, set

$$\bar{\delta} := \max(\delta_e + \delta_f, \delta_F),$$

and consider the sequence $(x_n)$ defined by (1.5).

Then, the iterates satisfy $\|x_n - x^\dagger\| \leq \gamma$ and in the noise-free case $\bar{\delta} = 0$, we have

$$\|x_n - x^\dagger\| = O(\sqrt{\alpha_n}, \quad n \to \infty.$$  

(2.5)

For $\bar{\delta} > 0$, assume that a stopping index $N$ is chosen such that

$$\alpha_N < \eta \bar{\delta} \leq \alpha_n, \quad 0 \leq n < N$$

(2.6)

with some constant $\eta > 0$ sufficiently large. Then, the error of the final approximation fulfills

$$\|x_N - x^\dagger\| = O(\sqrt{\bar{\delta}}, \quad \bar{\delta} \to 0.$$  

(2.7)

2.2. Proof of the theorem

Note that if $F = F_\delta = T: \mathcal{X} \to \mathcal{Y}$ is linear and bounded, then (1.5a) reduces to linear constrained Tikhonov regularization

$$x_n := \arg\min_{x \in \mathcal{C}} \left[\|Tx - g_\delta\|^2 + \alpha \|x - x_0\|^2\right]$$  

(2.8)

for a sequence of regularization parameter $\alpha = \alpha_n$. We first recall the stability and approximation properties in this case since they will be needed later in the proof.
Lemma 2.2.

(1) If
\[ x_\alpha := \arg\min_{x \in C} \left[ \| Tx - \overline{x}_\beta \|^2 + \alpha \| x - x_0 \|^2 \right] \]
for some \( \overline{x}_\beta \in \mathcal{Y} \), then
\[ \| x_\alpha - x_\alpha^0 \| \leq \frac{\| g_\delta - \overline{x}_\beta \|}{\sqrt{\alpha}}. \] (2.9)

(2) Let \( g = g_\delta \in T(C) \) and \( x_0 \in C \), and assume that the best-approximate solution \( x_\alpha^1 := \arg\min_{x \in C, Tx = g} \| x - x_0 \| \) satisfies the source condition
\[ x_\alpha^1 = P_C(T^* \omega + x_0) \] (2.10)
for some \( \omega \in \mathcal{Y} \). Then,
\[ \| x_\alpha - x_\alpha^1 \| = \sqrt{\alpha} \| \omega \| \quad \text{and} \quad \| Tx_\alpha - g \| = \alpha \| \omega \|. \] (2.11)

Proof. In (2.9), the special case \( x_0 = 0 \) is proved in [8, theorem 5.16]. The general case can be reduced to this special case by the substitution of variables \( z = x - x_0 \) since
\[ x_\alpha - x_0 = \arg\min_{z \in C - x_0} \left[ \| Tz + Tx_0 - g_\delta \|^2 + \alpha \| z \|^2 \right]. \] (2.12)
Equation (2.11) can be reduced to the case \( x_0 = 0 \), which is covered by [8, theorem 5.19], by the same substitution of variables and the identity \( P_{C-x_0}(T^* \omega) = P_C(T^* \omega + x_0) - x_0 \). \( \Box \)

Next we need a stability estimate with respect to perturbations of the operators, i.e. an estimate on the difference of
\[ x_1 := \arg\min_{x \in C} \left[ \| T_i(x - \tilde{x}) \|^2 + \alpha \| x - x_0 \|^2 \right], \quad i \in \{1, 2\}, \] (2.13)
where \( T_1, T_2 : \mathcal{X} \to \mathcal{Y} \) are bounded linear operators and \( \alpha > 0 \). Using the optimality conditions for the minimizers of (2.13), a straightforward computation gives an estimate of the form
\[ \| x_1 - x_2 \| \leq \frac{C}{\alpha} \| T_1 - T_2 \|. \] (2.14)
This simple estimate is not sufficient for our purposes, however. The following proposition shows that under a source condition we can obtain an improved estimate with a constant independent of \( \alpha \).

Proposition 2.3. Let \( x_1 \) and \( x_2 \) be defined by (2.13). Moreover, let the source condition
\[ \tilde{x} = P_C(T_2^* \omega + x_0) \] (2.15)
hold for some \( \omega \in \mathcal{Y} \) and let \( \tilde{x} = \arg\min_{x \in C, T_2 x = \tilde{x}} \| x - x_0 \| \). Then, the distance of \( x_1 \) and \( x_2 \) is bounded by
\[ \| x_1 - x_2 \| \leq \sqrt{\frac{2}{\alpha}} \| \omega \| \| T_1 - T_2 \|. \]

Proof. From lemma 2.2, part 2, we obtain
\[ \| T_2(x_2 - \tilde{x}) \| \leq \alpha \| \omega \| \] (2.16a)
\[ \| x_2 - \tilde{x} \| \leq \sqrt{\alpha} \| \omega \|. \] (2.16b)
Let $\chi_C : X \to \mathbb{R}^+$ be the proper, convex and lower semi-continuous functional
\[
\chi_C(x) := \begin{cases} 
0 & x \in C \\
\infty & \text{otherwise} 
\end{cases},
\]
and let $q_i \in \partial \chi_C(x_i)$; then, for $i \in \{1, 2\}$ the first order optimality condition for the minimizers $x_i$ is given by
\[
T^*_i T_i (x_i - \bar{x}) + \alpha (x_i - x_0) + q_i = 0.
\]
Subtracting these equations gives
\[
T^*_i T_i (x_1 - x_2) + \alpha (x_1 - x_2) + (q_1 - q_2) = (T^*_2 T_2 - T^*_1 T_1) (x_2 - \bar{x}).
\]
Now taking the inner product with $x_1 - x_2$, we obtain
\[
\|T_1 (x_1 - x_2)\|^2 + \alpha \|x_1 - x_2\|^2 + (q_1 - q_2, x_1 - x_2) = \langle (T^*_2 - T^*_1) T_2 (x_2 - \bar{x}), x_1 - x_2 \rangle + \langle (T_2 - T_1) (x_2 - \bar{x}), T_1 (x_1 - x_2) \rangle.
\]
Together with the inequalities (2.16), (2.17) and (2.18), we obtain
\[
\frac{\alpha}{2} \|x_1 - x_2\|^2 \leq \frac{1}{2\alpha} \|T_2 (x_2 - \bar{x})\|^2 \|T_1 - T_2\|^2 + \frac{\alpha}{2} \|x_1 - x_2\|^2 + \frac{3}{4} \|x_2 - \bar{x}\|^2 \|T_1 - T_2\|^2
\]
which implies the assertion. \hfill \Box

Now we are able to formulate a recursive error estimate for the IRGNM with the closed convex constraint.

**Lemma 2.4.** Assume that (1.1) and (1.5)–(2.3) are satisfied and that $x_n \in C$ with $\|x_n - x^\dagger\| \leq \gamma$; then, the error $e_n := x_n - x^\dagger$ satisfies
\[
\|e_{n+1}\| \leq \frac{1}{\sqrt{\alpha_n}} \frac{L}{2} \|e_n\|^2 + \sqrt{\frac{3}{2}} \rho \|e_n\| + \frac{1}{\sqrt{\alpha_n}} (\delta_k + \delta_F) + \sqrt{\alpha_n \rho} + \sqrt{\frac{3}{2}} \rho \delta_F.
\]

**Proof.** At first we note that one can express the noisy data as $g_\delta = F_\delta(x^\dagger) + \xi + \epsilon$, with $\|\xi\| \leq \delta_F$ and $\|\epsilon\| \leq \delta_F$. Further since $x_n \in C$ and $F_\delta$ is Gateaux differentiable with derivatives that fulfill condition (2.3), we can express $F_\delta(x^\dagger)$ in a Taylor series
\[
F_\delta(x^\dagger) = F_\delta(x_n) + F_\delta'[x_n](x^\dagger - x_n) + r_n(x^\dagger - x_n),
\]
where
\[
\|r_n(x^\dagger - x_n)\| \leq \frac{L}{2} \|x^\dagger - x_n\|^2.
\]
Thus, we can rewrite the IRGNM functional (1.5a) of the $n$th iteration step, defining $T_n := F'_{I}[x_n]$, as
\[
\|T_n x - (T_n x_n - F_0(x_n) + g_0)\|^2 + \alpha_n\|x - x_0\|^2 = \|T_n (x - x^\dagger) - r_n(x^\dagger - x_0) - \xi - \epsilon\|^2 + \alpha_n\|x - x_0\|^2.
\]
(2.22)
Now we can decompose the distance of the solution $x_{n+1}$ of the $(n + 1)$st iteration to the exact solution $x^\dagger$ using the triangle inequality
\[
\|x_{n+1} - x^\dagger\| \leq \|x_{n+1} - x_{a,n}\| + \|x_{a,n} - x_{a,n}\| + \|x_{a,n} - x^\dagger\|
\]
(2.24) with
\[
x_{a,n} = \arg\min_{x \in C} \|T_n (x - x^\dagger) - r_n(x^\dagger - x_0) - \xi - \epsilon\|^2 + \alpha_n\|x - x_0\|^2.
\]
(2.27)
It follows from lemma 2.2, part 1, that
\[
\|x_{n+1} - x_{a,n}\| \leq \frac{\|r_n(x^\dagger - x_0) + \xi + \epsilon\|}{\sqrt{\alpha_n}}.
\]
(2.25)
With (2.21), $\|\xi\| \leq \delta_F$ and $\|\epsilon\| \leq \delta_F$, we obtain
\[
\|x_{n+1} - x_{a,n}\| \leq \frac{1}{\sqrt{\alpha_n}} \left(\frac{L}{2}\|x_n - x^\dagger\|^2 + \delta_F + \delta_F\right).
\]
(2.26)
The second term in (2.24) can be estimated using proposition 2.3 with $T_1 = T_n$, $T_2 = F'[x^\dagger]$ and $\hat{\epsilon} = \delta_F$, which gives
\[
\|x_{a,n} - x_{a,n}\| \leq \sqrt{\frac{3}{2}} \rho \|T_n - F'[x^\dagger]\|
\leq \sqrt{\frac{3}{2}} \rho \left(\|T_n - F'_0[x^\dagger]\| + \left\|F'_0[x^\dagger] - F'[x^\dagger]\right\|ight)
\leq \sqrt{\frac{3}{2}} \rho \left(L\|x_n - x^\dagger\| + \delta_F\right).
\]
(2.27) where we used (2.3) and (2.1c) to obtain the last inequality of (2.27). For the third term in (2.24), we again use lemma 2.2, part 2, to obtain
\[
\|x_{a,n} - x^\dagger\| \leq \sqrt{\alpha_n}\rho.
\]
(2.28)
Combining (2.24), (2.26), (2.27) and (2.28) gives the assertion.

Estimate (2.19) is of the form used in [5] and [14], so we can use a similar proof now to obtain the main result.

**Proof of theorem 2.1.** It follows from lemma 2.4 that the quantities $\Theta_n := \frac{\|\epsilon_0\|}{\sqrt{\alpha_n}}$ fulfill the inequality
\[
\Theta_{n+1} \leq a + b\Theta_n + c\Theta_n^2
\]
with $a := \sqrt{\delta}\rho$ for $\delta = 0$ and $a := \sqrt{\delta}(\rho + \frac{\delta\rho\sqrt{\delta}}{\delta} + \sqrt{\frac{3}{2}\rho}\frac{\delta\rho}{\sqrt{\delta}})$ for $\delta > 0$, $b := \sqrt{\frac{3}{2}\delta}\rho L$ and $c := \sqrt{\frac{3}{2}}\rho$. Let $t_1$ and $t_2$ be solutions to the fixed-point equation $a + bt + ct^2 = t$, i.e.
\[
t_1 := \frac{2a}{1 - b + \sqrt{(1 - b)^2 - 4ac}}, \quad t_2 := \frac{1 - b + \sqrt{(1 - b)^2 - 4ac}}{2c},
\]
(2.30)
3. Joint reconstruction of object and phase in 4Pi microscopy

Before we describe our mathematical model of the 4Pi imaging process precisely, let us discuss this technique in more detail. Confocal fluorescence microscopy allows for the reconstruction of three-dimensional fluorescent marker densities in living cells by scanning a specimen at a grid of points \( \{ x_j \in \mathbb{R}^3 : j = 1, \ldots, N \} \). Laser light is focused to a small area by objective lenses, and a pinhole is used to collect only fluorescence photons emitted close to the focus \( x_j \) (cf [19]). The psf \( h(x - y) \) in (1.2) is the probability that a fluorescence photon emitted at \( y \) is detected if the point \( x \) is illuminated. Data consist of photon count numbers \( G_j \), \( j = 1, \ldots, N \), which are Poisson-distributed random numbers with mean \( EG_j = g(x_j) \).

In 4Pi microscopy, the same data model holds true, but \( g \) is given by \( g = F_{4\pi}(f, \phi) \) with the integral operator (1.3). For its kernel, we use the more accurate model

\[
p(z, \phi) = |E_1(z) - \exp(\imath \phi)|E_2(z)|^2 h_{\text{det}}(z) \tag{3.1}
\]

(see [21]) instead of the simple model (1.4). Here \( E_{1,2} \) are counterpropagating focal fields and \( h_{\text{det}} \) is the detection psf for which we used implementations available under www.inspector.de.

3.1. Forward operator and its derivative

We first define appropriate function spaces for the integral operator \( F_{4\pi} \) in (1.3). We assume that \( f \) is supported in some cube \( \Omega := \prod_{j=1}^3 [-R_j, R_j] \) and choose \( L^2(\Omega) \) with the standard \( L^2 \)-norm as a function space for the object \( f \). We may further assume that \( p(\cdot, \phi) \) is supported
Figure 2. (a) A slice of real three-dimensional 4Pi-data, where in the approximate center the waves were interfering destructively. From these data the reconstructions of object (c) and phase (d) have been obtained with the constrained IRGNM for $f_0 = 0$ and $\phi_0 = 0$. The reconstruction of the phase reflects the constructive interference on the left and right side of the data and the destructive interference in the center. The modeled psf (for constructive interference) is depicted in (b) together with indications on the scale and the optical axis (represented by the arrow). To reconstruct the phase, we used a basis of polynomials with maximal degree 7 in each dimension.

...in some (typically much smaller) cube $\prod_{j=1}^3 [-r_j, r_j]$ for all $\varphi$ such that $g$ is supported in $\Omega' := \prod_{j=1}^3 [-R_j - r_j, R_j + r_j]$.

A reason why joint reconstruction of $f$ and $\phi$ from data $g$ often works even though the problem is formally underdetermined is that $\phi$ can be assumed to be very smooth (often it is even assumed to be constant). Therefore, we choose the Sobolev space $H^2(\Omega')$ for $\phi$ with the norm $\|\phi\|_{H^2(\Omega')} := \left( \int_{\Omega'} |\phi|^2 + |\nabla \phi|^2 + |\Delta \phi|^2 \, dx \right)^{1/2}$ to achieve smooth interpolation in areas where no information on $\phi$ is contained in the data. (This is the case, e.g., in areas where $f$ is constant. But in such areas $\phi$ is irrelevant for the primary goal to recover $f$.)

The data misfit term should reflect the distribution of data errors. Since our data are Poisson distributed, a natural data misfit term would be the negative log-likelihood function, which is given by $\sum_{j=1}^N g(x_j) - G_j \log g(x_j)$. We define a piecewise constant approximation $g^\delta \in L^2(\Omega')$ of the data $(G_j)$ and approximate the negative log-likelihood by a second order Taylor expansion at $G_j$. This leads to a weighted $L^2$ space $\mathcal{Y} := L^2(\Omega', w)$ with the norm $\|g\|_{\mathcal{Y}}^2 = \int_{\Omega'} g^2(x) w(x) \, dx$ and the weight function

$$w(x) = \frac{1}{2 \max(g^\delta(x), c)}.$$  

Here $c > 0$ is a small constant avoiding division by zero. As usually multiple weaker sources contribute to the data noise, a suitable choice of $c$ is the background noise level. Better approximations to the Poisson log likelihood can be achieved by taking a Taylor expansion at $g_0 = F_{4Pi}(f_0, \phi_0)$ and iterating in a sequential quadratic programming manner, but for the count rates in our experimental data this did not lead to a noticeable improvement.
Figure 3. (a) and (b) Reconstructions of object and phase respectively from the data shown in
figure 2(a), which have been obtained by the unconstrained IRGNM. The phase is very badly
reconstructed which leads to remaining sidelobes in the object reconstruction. This is most eminent
in the center where the psf features destructive interference. The same deficiencies can be observed
in (c) and (d), where the nonnegativity constraint has been incorporated by a simple projection
after each step. All of the reconstructions depicted in figures 2 and 3 were performed with the same
regularization parameters.

In summary, the precise definition of our forward operator is as follows:

\[ F_{4\pi} : L^2(\Omega) \times H^2(\Omega') \to L^2(\Omega', w) \]

\[ (F_{4\pi}(f, \phi))(x) := \int_{\Omega} p(x - y, \phi(x)) f(y) dy, \quad x \in \Omega'. \] (3.2)

Note that \( F_{4\pi} \) does not change if \( p(\cdot, \phi) \) is replaced by its periodic extension with the period

cell \( \Omega' \).

**Lemma 3.1.** If \( p : \prod_{j=1}^J (\mathbb{R}/(2(R_j + r_j)\mathbb{Z})) \times (\mathbb{R}/\pi\mathbb{Z}) \to \mathbb{R} \) is continuous and continuously
differentiable with respect to its last argument, then the operator \( F_{4\pi} \) defined in (3.2) is Fréchet

differentiable on \( X \) with

\[ F'_{4\pi}[f, \phi](h_f, h_\phi)(\xi) = \int_{\Omega} \left[ p(y - x, \phi(x)) h_f(y) + \frac{\partial p}{\partial \phi}(y - x, \phi(x)) f(y) h_\phi(x) \right] dy, \] (3.3)

and the adjoint of \( F'[f, \phi] : L^2(\Omega) \times H^2(\Omega) \to L^2(\Omega', w) \) is given by

\[ F'_{4\pi}[f, \phi]^\ast \hat{g} = \left( j^* \left( gw \int_{\Omega} \frac{\partial p}{\partial \phi}(\cdot - y, \phi(\cdot)) f(y) dy \right) \right) \] (3.4)

where \( j : H^2(\Omega) \to L^2(\Omega') \) is the embedding operator. Moreover, \( F'_{4\pi} \) satisfies the Lipschitz

condition (2.3) if \( \frac{\partial p}{\partial \phi} \) is uniformly Lipschitz continuous with respect to its last argument.

**Proof (sketch).** The Fréchet differentiability of \( F \) and equation (3.3) follow from a Taylor

expansion of the kernel \( p \) with standard estimates on the Taylor remainder and the continuity
Figure 4. (a) and (b) A simulated object and phase, and (c) the corresponding 4Pi-data perturbed with Poisson-noise. (d) and (e) The reconstructions of object and phase respectively from this noisy data obtained with the constrained IRGNM. (f) The residual $\| g_\delta - F(f_n, \phi_n) \|_{L^2}$, the object error $\| f_n - f^\dagger \|_{L^2}$, and the phase error $\| \phi_n - \phi^\dagger \|_{L^2}$ are plotted over the iteration index $n$. (g)–(i) Analogous to (d)–(f) with noisy data $g_\delta$ replaced by exact data $F(f^\dagger, \phi^\dagger)$. The residual

\[ \| g_\delta - F(f_n, \phi_n) \|_{L^2} \]

of the embedding $H^2(\Omega') \hookrightarrow L^\infty(\Omega')$. The adjoint $F^*[f, \phi]_{L^2}$ of the continuous extension $F[f, \phi]_{L^2}$ of $F[f, \phi]$ to $L^2(\Omega) \times L^2(\Omega')$ can be computed by interchanging the order of integration. Then, (3.4) follows from $F^*[f, \phi]^* = \left( \frac{i}{0} \phi \right) F^*[f, \phi]_{L^2} = \left( \frac{0}{\phi} \right) F^*[f, \phi]_{L^2}$. The statement on Lipschitz continuity is straightforward.

The crucial observation for an efficient implementation of $F_{4\Pi}$ and $F_{4\Pi}'$ is that $p$ can be separated into

\[ p(z, \varphi) = \sum_{m=-M}^{M} \exp(im\varphi)A_m(z) \]
with $A_m \in L^2(\prod_{j=1}^{3}(R/(2(R_j + r_j)Z)))$. This was observed by Baddeley et al in [1] for the approximation (1.4) and by Vicidomini et al in [21] for the model (3.1). Hence,

$$(F_{4Pi}(f,\phi))(x) = \sum_{m=-M}^{M} \exp(i m \phi(x)) \int_{\Omega} A_m(x - y) f(y) dy, \quad x \in \Omega'.$$

Here $f$ is extended by 0 in $\Omega' \setminus \Omega$ (zero-padding). The convolution integrals can be evaluated efficiently using FFT. An analogous procedure can be applied for the evaluation of $F'[f, \phi]$ and its adjoint.

We approximated the phase $\phi$ using tensor products of Chebychev polynomials for which the Gramian matrix with respect to the $H^2$ inner product can be computed explicitly.

### 3.2. Implementation and necessity of the nonnegativity constraint

We solve the constrained quadratic minimization problems

$$(f_{n+1}, \phi_{n+1}) := \text{argmin}_{(f, \phi) \in L^2(\Omega) \times H^2(\Omega), \quad f \geq 0 \text{ a.e.}} \|F_{4Pi}([f_n, \phi_n])(f, \phi) - g_n\|^2 + \alpha_n \|f_n - (f_0, \phi_0)\|^2, (3.5)$$

with

$$g_n := F_{4Pi}([f_n, \phi_n])(f_n, \phi_n) - F_{4Pi}((f_n, \phi_n)) + g_\delta$$

using the semi-smooth Newton (SSN) method (cf [13]). In each step of this method, an unconstrained, positive definite linear system has to be solved, which is done by the conjugate...
gradient method. In figure 2, the reconstruction of a fluorophore density and the phase from a 2D-slice of real 4Pi data is shown.

To demonstrate the necessity to incorporate a nonnegativity constraint into the minimization problem, in figure 3 we display reconstructions from the same data, without constraint and with simply projecting onto $C$ after an unconstrained IRGNM step, i.e. for the iteration schemes

$$
(f^u_{n+1}, \phi^u_{n+1}) := \arg\min_{(f, \phi) \in L^2(\Omega) \times H^2(\Omega)} \left[ \| F_{4\Pi}^\prime \left[ (f^u_n, \phi^0_n) \right] (f, \phi) - g_n \|^2 + \alpha_n \| (f, \phi) - (f_0, \phi_0) \|^2 \right],
$$

$$
(f^p_{n+1}, \phi^p_{n+1}) := P_C \arg\min_{(f, \phi) \in L^2(\Omega) \times H^2(\Omega)} \left[ \| F_{4\Pi}^\prime \left[ (f^p_n, \phi^0_n) \right] (f, \phi) - g_n \|^2 + \alpha_n \| (f, \phi) - (f_0, \phi_0) \|^2 \right].
$$

Here the metric projection is given by $P_C (f, \phi) = (\max (f, 0), \phi)$. Comparing the reconstructions of figures 2 and 3, it is obvious that the incorporation of the nonnegativity constraint in the minimization problem is necessary for accurate reconstructions of the phase.

A further option pursued in [21] is to update $f$ and $\phi$ in alternating manner such that in each update step for $f$, a constrained minimization problem for $f$ only instead of both $f$ and $\phi$ has to be solved. However, such a procedure requires significantly more iteration steps.

### 3.3. Results for simulated and experimental data

Figure 4 shows reconstructions from simulated two-dimensional noisy and exact data. The exact phase is chosen as a shifted sum of a sine and arctan function, which does not belong to a finite-dimensional polynomial subspace. For the reconstruction of the phase, we choose polynomials of maximal degree 7 in each dimension, which is sufficient to capture the main features of the exact phase. Reconstructions with polynomials of higher degrees did not lead to better reconstructions of the phase. For exact data, the sidelobes are removed completely, and...
Figure 7. (a) The reconstruction of the object from the data shown in figure 6. (b) The corresponding reconstruction of the phase is depicted. The variation of the reconstructed phase corresponds to the variation of the side lobes in the data, which have been removed nearly completely in the reconstruction of the object.

for noisy data at the given count rate only very little of the sidelobes is left in the reconstruction. The required number of SSN steps increases with $n$. To give an idea, we mention that less than 8 SSN steps were needed for $n \leq 21$ with less than 80 CG steps in each SSN step, and for $n = 30$ the algorithm required 49 SSN steps with less than 600 CG steps. We must say that the stopping indices for the Gauss–Newton iteration are chosen somewhat arbitrarily in this paper. Numerical tests concerning stopping rules for the IRGNM iteration can be found in [20]. The development of a good stopping rule for the kind of errors considered in this paper, nonlinear operators and convex constraints is an interesting topic for future research.

In figure 5, we chose an object which is constant in a region, and hence the data carry no information on the phase there. Due to the $H^2$-phase penalty term, the phase is interpolated smoothly in this area and recovered quite well, except in dark areas close to the boundary. In contrast, the reconstruction of the object exhibits a grainy structure in the central area. This is a consequence of choosing the $L^2$ norm as object penalty. Since we have found a good approximation $\phi_{\text{app}}$ of the phase, we can compute a better reconstruction of the object in a second step by solving an inverse problem for the linear operator $f \mapsto F(f, \phi_{\text{app}})$. The result in figure 5(f) was computed using an expectation-maximization method with a TV penalty term and Bregman iterations as described in [6].

Figure 6 shows cuts through three-dimensional experimental data. The corresponding reconstructions of object and phase are shown in figure 7. Note that due to the simultaneous reconstruction of the phase function, the non-symmetric sidelobes in the data have been removed in the object reconstruction.

Including the zero padding, the data contained approximately 2 million voxels. The phase has been approximated by Chebychev polynomials of maximal degree 3 in each dimension.

4. Conclusions

We have suggested and analyzed a version of the IRGNM respecting convex constraints and proved convergence rates under a projected Hölder-type source condition. Our analysis includes both errors in the data and in the operator.
Moreover, we have demonstrated that our modification of the IRGNM is crucial for the simultaneous reconstruction of object and phase from 4Pi microscopic data. With reliable reconstructions of the space-varying phase difference, it is possible to remove side lobe artifacts as they occur in methods reconstructing only the object by inverting a linear operator. This enhances the field of application of 4Pi microscopy to specimen with strong variations of the refractive index where spatial variations of the phase difference are inevitable.

Acknowledgments

We would like thank Andreas Schönle and Giuseppe Vicidomini (MPI biophysical chemistry, Göttingen) for their support concerning microscopic data and information on 4Pi microscopy. We further thank Jan Keller for his matlab code implementing the 4Pi-psf model (3.1). Finally, we gratefully acknowledge financial support by BMBF (German Federal Ministry for Education and Science) under the project INVERS.
