(Dated: October 30, 2018)

We investigate the short-time universal behavior of the two dimensional Ashkin-Teller model at the Baxter line by performing time-dependent Monte Carlo Simulations. First, as preparatory results, we obtain the critical parameters by searching the optimal power law decay of the magnetization. Thus, the dynamic critical exponents \( \theta_m \) and \( \theta_p \), related to the magnetic and electric order parameters, as well as the persistence exponent \( \theta_p \), are estimated using heat-bath Monte Carlo simulations. In addition, we estimate the dynamic exponent \( z \) and the static critical exponents \( \beta \) and \( \nu \) for both order parameters. We propose a refined method to estimate the static exponents that considers two different averages: one that combines an internal average using several seeds with another which is taken over geographic variations in the power laws. Moreover, we also performed the bootstrapping method for a complementary analysis. Our results show that the ratio \( \beta/\nu \) exhibits universal behavior along the critical line corroborating the conjecture for both magnetization and polarization.

INTRODUCTION

In 1971 Baxter [1] calculated the free energy of the symmetric eight-vertex model and found out for the first time a continuous dependence of the critical exponents on the coupling coefficients of the model. This result seemed, in principle, to contradict the universality hypothesis [2] which suggests that the critical exponents should be constant and a variation would be possible only in the case of a change in the symmetry. Despite this apparent contradiction, Kadanoff and Wegner [5] and Wu [6], showed independently a connection between the continuous variation of those exponents and the presence of a marginal operator in the Hamiltonian by demonstrating the equivalence of this model with an Ising model in a square lattice without field. In this formulation, besides the interactions between next-nearest-neighbors, there is still a four-body interaction and the Hamiltonian is written as [7]:

\[
\beta H_{SV} = -J_1 \sum_{i,j=1}^{L} \sigma_{i,j+1} \sigma_{i+1,j} - J_2 \sum_{i,j=1}^{L} \sigma_{i,j} \sigma_{i+1,j+1} - \lambda \sum_{i,j=1}^{L} \sigma_{i,j} \sigma_{i,j+1} \sigma_{i+1,j} \sigma_{i+1,j+1},
\]

where \( \sigma_{i,j} = \pm 1 \) is the Ising spin at the site \((i,j)\) of the lattice, \( \beta = (k_BT)^{-1} \), \( k_B \) and \( T \) being respectively the Boltzmann constant and the temperature of the system. The sums run over all spins and periodic boundary conditions are assumed: \( \sigma_{L+1,j} = \sigma_{1,j} \) and \( \sigma_{i,L+1} = \sigma_{i,1} \). The spins are coupled by the coefficient \( J_1 \) in one direction and by \( J_2 \) in the other one and the coefficient \( \lambda \) couples four spins.

The symmetric eight-vertex model, also known as Baxter model, has only one critical line, where \( J_1 = J_2 = J \). This line is given by the equation [7]

\[
\exp(-2\lambda) = \sinh(2J).
\]

Besides the eight-vertex model there are other models that exhibit nonuniversality, e.g. the Ising model with competing interactions [8] and the Ashkin-Teller model [9]. The latter was introduced in 1943 to describe a four-component system with nearest-neighbors interactions, displaced on a two-dimensional lattice. Soon after the Baxter’s work, Fan [10] showed that the Ashkin-Teller (AT) model could be represented by two superposed Ising systems and coupled by a four-body interaction coefficient.

In this representation the Hamiltonian for the AT model is given by two-species model:

\[
\beta H_{AT} = -K_1 \sum_{i,j=1}^{L} \sigma_{i,j} (\sigma_{i,j+1} + \sigma_{i+1,j})
- K_2 \sum_{i,j=1}^{L} \mu_{i,j} (\mu_{i,j+1} + \mu_{i+1,j})
- K_4 \sum_{i,j=1}^{L} \sigma_{i,j} \mu_{i,j} (\sigma_{i+1,j} \mu_{i+1,j} + \sigma_{i,j} \mu_{i,j+1}),
\]

where \( \sigma_{i,j} = \pm 1, \mu_{i,j} = \pm 1 \) is the Ising spin at the site \((i,j)\) of the sublattice \( \sigma \) (\( \mu \)), \( K_1 \) (\( K_2 \)) is the coupling coefficient of the spin variable \( \sigma_{i,j} \) (\( \mu_{i,j} \)), and \( K_4 \) is the four-body coefficient which couples the two Ising systems. The sums run over all spins and periodic boundary conditions are assumed: \( \sigma(\mu)_{L+1,j} = \sigma(\mu)_{1,j} \) and \( \sigma(\mu)_{i,L+1} = \sigma(\mu)_{i,1} \).

Wegner [11] showed that carrying out a duality transformation in one of the lattices (\( \mu \), for example), one can map the AT model into a staggered eight-vertex model. This alternation does not disappears even for the isotropic model \( K_1 = K_2 = K \) except at the self-dual line

\[
\exp(-2K_4) = \sinh(2K),
\]

where the AT model becomes equivalent to an isotropic eight-vertex model with four-spin coupling constant (\( \lambda \))
CRITICAL DYNAMICS FOR THE MODEL

Until a few years ago, it was a common sense that no universal behavior could be found in systems during the initial stage of the relaxation process. As a result, critical properties of these systems, like transition temperatures and critical exponents, were obtained only in equilibrium. The numerical calculation of such values was not a simple task, due to the severe critical slowing down which takes place in the vicinity of the criticality. Many efforts have been made to circumvent this difficulty, for instance, the cluster algorithm [15, 16] has proven to be very efficient in the study of static properties of systems. Nevertheless, in that case the original dynamic class of universality is violated, leading to normally small values for the dynamic critical exponents. Another way to avoid problems with the critical slowing down was proposed by Janssen et al. [17] and Huse [18]. Using renormalization group techniques and numerical calculation, respectively, they showed that the critical relaxation of a system initially at very high temperature exhibits universality and scaling behavior even in the initial steps of evolution. The so-called short-time regime became therefore an important method in the study of phase transitions and critical phenomena.

The dynamic scaling relation obtained by Janssen et al. for the \( k \)-th moment of the magnetization, extended to systems of finite size [19, 20], is written as

\[
\overline{M^k}(t, \tau, L, m_0) = b^{-k\nu} \overline{M^k}(b^{-\zeta} t, b^{\xi} \tau, b^{-1} L, b^{\eta} m_0).
\]  (9)

Here \( t \) is the time evolution, \( b \) is an arbitrary spatial rescaling factor, \( \tau = (T - T_c)/T_c \) is the reduced temperature, and \( L \) is the linear size of the square lattice. This evolution is governed by a new dynamic exponent \( \theta \) independent of the well known static critical exponents and the dynamic exponent \( z \). This new exponent characterizes the so-called critical initial slip, the anomalous behavior of the magnetization when the system is quenched to the critical temperature \( T_c \). In addition, a new critical exponent \( \theta_0 \) which represents the anomalous dimension of the initial magnetization \( m_0 \) is introduced to describe the dependence of the scaling behavior on the initial conditions. This exponent is related to \( \theta \) as \( \theta_0 = \theta z + \beta/\nu \).

From Eq. (9), the scaling relations for the \( k \)-th moment of the magnetization and polatization of the Ashkin-Teller model are given, respectively, by

\[
\overline{M^k}(t, \tau, L, m_0) = b^{-k\nu_m} \overline{M^k}(b^{-\zeta_m} t, b^{\xi_m} \tau, b^{-1} L, b^{\eta_m} m_0)
\]  (10)

and

\[
\overline{P^k}(t, \tau, L, p_0) = b^{-k\nu_p} \overline{P^k}(b^{-\zeta_p} t, b^{\xi_p} \tau, b^{-1} L, b^{\eta_p} p_0),
\]  (11)

where \( p_0 \) is the initial polarization of the system. Here, differently from \( \langle O \rangle \), the average \( \overline{O} \) describes an average over different random evolutions and over initial conditions of the system.

In this work the dynamic critical exponents \( \theta_m \) and \( \theta_p \) are obtained through two different approaches, a time correlation of the magnetization [21]

\[
Q_M(t) = \overline{M(0)M(t)} \sim t^{\theta_m}
\]  (12)
and

\[ Q_P(t) = \mathcal{P}(0)P(t) \sim t^{\theta_p}, \]  

(13)

and the scaling forms

\[ \mathcal{M}(t) \sim m_0 t^{\theta_m}, \]  

(14)

and

\[ \mathcal{P}(t) \sim p_0 t^{\theta_p}. \]  

(15)

In order to see such power law behaviors we can look into some details of scaling relation. Taking into account the magnetization (we have a similar analysis for the polarization), after the scaling \( b^{-1}L = 1 \) at the critical temperature \( T = T_c \), the first \((k = 1)\) moment of the order parameter is \( \mathcal{M}(t, L, m_0) = L^{-\beta/\nu} \mathcal{M}(L^{-z}t, L^{-\theta_m}m_0) \). Denoting \( u = tL^{-z} \) and \( w = L^{-\theta_m}m_0 \), one has \( \mathcal{M}(u, w) = L^{-\beta/\nu} \mathcal{M}(L^{-z}t, L^{-\theta_m}m_0) \). Hence, the derivative with respect to \( L \) is given by

\[
\partial_L \mathcal{M} = (-\beta/\nu)L^{-\beta/\nu-1} \mathcal{M}(u, w) \\
+ L^{-\beta/\nu}[\partial_u \mathcal{M}\partial_L u + \partial_w \mathcal{M}\partial_L w],
\]

where one has explicitly \( \partial_u u = -ztL^{-z-1} \) and \( \partial_L w = x_0 m_0 L^{-x_0-1} \). In the limit \( L \to \infty \), which implicates \( \partial_L \mathcal{M} \to 0 \), one has \( x_0 w \partial_u \mathcal{M} - z u \partial_u \mathcal{M} - \beta/\nu \mathcal{M} = 0 \). The separability of the variables \( u \) and \( w \), i.e., \( \mathcal{M}(u, w) = M_u(u)M_w(w) \) leads to

\[
x_0 w M'_w/M_w = \beta/\nu + z u M'_u/M_u,
\]

where the prime means the derivative with respect to the argument. Since the left-hand side of this equation depends only on \( w \) and the right-hand side depends only on \( u \), both sides must be equal to a constant \( c \). Thus, \( M_u(u) = c e^{cz}/(-\beta/\nu v) \) and \( M_w(w) = w^{c/x_0} \), resulting in \( \mathcal{M}(u, w) = M_0 e^{c/x_0} \beta/\nu v (c-\beta/\nu)/z \). Returning to the original variables, one has

\[ \mathcal{M}(t, L, m_0) = m_0 e^{c/x_0} \beta/\nu v (c-\beta/\nu)/z. \]  

(16)

By choosing \( c = x_0 \) at criticality \((\tau = 0)\), one obtains \( \mathcal{M}_{m_0} \sim m_0 t^{\theta_m} \), as previously reported in Eq. \( 14 \) and \( 15 \), where \( \theta = (x_0 - \beta/\nu)/z \). This corresponds to a regime of small initial magnetization soon after a finite time scaling \( b = t^{1/z} \) in Eq. \( 9 \). We therefore obtain \( \mathcal{M}(t, m_0) = t^{-\beta/\nu} \mathcal{M}(1, t^{\theta_m}m_0) \). By calling \( x = t^{\theta_m}m_0 \), an expansion of the averaged magnetization around \( x = 0 \) results in \( \mathcal{M}(1, x) = \mathcal{M}(1, 0) + \partial_x \mathcal{M} \bigg|_{x=0} x + O(x^2) \). By construction \( \mathcal{M}(1, 0) = 0 \) and, since \( u = t^{\theta_m}m_0 \ll 1 \), we can discard quadratic terms resulting similarly in \( \langle M \rangle_{m_0} \sim m_0^\theta_m \). This anomalous behavior of initial magnetization is valid only for a characteristic time scale \( t_{\text{max}} \sim m_0^{-\frac{1}{z_0}} \).

Another dynamic critical exponent is obtained far from equilibrium by following the behavior of the global persistence probability \( G(t) \) \cite{22}, the probability of the order parameter does not change its sign up to the time \( t \). For the magnetization and polarization, it decays respectively as

\[ G_M(t) \sim t^{-\theta_m}, \]

(17)

and

\[ G_P(t) \sim t^{-\theta_p}, \]

(18)

where the exponents \( \theta_m \) and \( \theta_p \) are the global persistence exponents of the magnetization and polarization, respectively.

As pointed out in Ref. \cite{22} and shown in several works \cite{23, 24}, the global persistence exponent is an independent critical index and is closely related to the non-Markovian character of the process. On the contrary, if the process would be a Markovian one, this exponent should obey the equation

\[ \theta = -\theta + \frac{d}{z} - \frac{\beta}{\nu}. \]

(19)

The dynamic critical exponents \( z_m \) and \( z_p \) are obtained using the ratios \cite{37}

\[ F_{2_M}(t) = \frac{M(t)^2}_{m_0=0} \sim t^{d/z_m} \]  

(20)

and

\[ F_{2_P}(t) = \frac{P(t)^2}_{p_0=0} \sim t^{d/z_p}, \]  

(21)

where \( d \) is the dimension of the system and the average is over different samples with initial states \( m_0 \) and \( p_0 \), respectively.

The first moment of the magnetization in Eq. \( 20 \) (the denominator) is obtained by making \( c = 0 \) in Eq. \( 16 \) and considering which that such power law decays from ordered initial state \((m_0 = 1)\). Since the system has no dependence on initial conditions, one has

\[ \mathcal{M}_{m_0=1}(t) \sim t^{-\beta_m/\nu z_m} \]  

(22)

The same analysis can be done for the polarization obtaining

\[ \mathcal{P}_{p_0=1}(t) \sim t^{-\beta_p/\nu z_p}. \]  

(23)

On the other hand, the second moment of the magnetization in Eq. \( 20 \) (the numerator) can be written as

\[ \mathcal{M}^2_{m_0=0} = \frac{1}{L^{2d}} \sum_{i=1}^L \langle \sigma_i^2 \rangle + \frac{1}{L^{2d}} \sum_i \langle \sigma_i^\dagger \sigma_j \rangle \approx L^{-d} \]

\[ \langle \sigma_i^\dagger \sigma_j \rangle \approx L^{-d} \]

(24)

\[ \mathcal{P}_{p_0=1}(t) \sim t^{-\beta_p/\nu z_p}. \]  

(25)
for a fixed $t$. By taking into account $k = 2$ in Eq. (10) with $b = t^{1/z_m}$ and considering that the spin-spin correlation $\langle \sigma_i \sigma_j \rangle$ is negligible form $m_0 = 0$, we obtain

$$M^2_{m_0=0}(t, L) \approx t^{2b_m} M^2_{m_0=0}(1, bL)$$

$$= t^{2b_m} (bL)^{-d}$$

$$\sim t^{(d-2b_m)/z_m}$$

and similarly,

$$P^2_{m_0=0}(t, L) \sim t^{(d-2b_m)/z_p}$$

for the second moment of the polarization. Therefore, the power laws given by Eqs. (20) and (21) can be easily verified.

This approximation proved to be very efficient in estimating the exponent $z$, according to results for the Ising model, the $q = 3$ and $q = 4$ Potts models, the tricritical point of the Blume-Capel model [38], metamagnetic model [39], ANNNI model [40], spin models based on generalized Tsallis statistics [41], Z5 model [42], the Baxter-Wu model [43], the double-exchange model [44], Heisenberg model [45] and even models without defined Hamiltonian (see, for example, Refs. [27, 45]).

The static exponents must be obtained via other power laws. When $L \rightarrow \infty$, one has $M(t, \tau) = b^{-k/\nu} M(b^{-\gamma} t, b^{1/\nu} \tau)$. By scaling $b^{-\gamma} t = 1$, we have $M(t, \tau) = t^{-\beta/(\nu z)} f(t^{1/(\nu z)} \tau)$ where $f(x) = M(1, x)$ and so $\partial \ln M(t, \tau) / \partial \tau = \frac{1}{M(t)} \partial \ln M = t^1/(\nu z) f(t^{1/(\nu z)} \tau)$. Therefore we have

$$D_M(t) = \left. \frac{\partial \ln M(t, \tau)}{\partial \tau} \right|_{\tau = 0} = f_0 \cdot t^{1/(\nu z m)} \sim t^{\phi_m}$$

(26)

where $f_0 = f(0)$ is a constant and $\phi_m = 1/(\nu m z_m)$. Since we have already estimated the exponent $z_m$ (Eq. (20)), we are able to obtain $\nu m$. With these two exponents in hand, we can obtain $\beta_m$ by estimating the exponent $\mu_m = \beta_m/(\nu m z_m)$ from Eq. (22). By changing $M$ by $P$, we have

$$D_P(t) = \left. \frac{\partial \ln P(t, \tau)}{\partial \tau} \right|_{\tau = 0} \sim t^{\phi_p}$$

(27)

with $\phi_p = 1/(\nu p z_p)$, where the exponents $\nu p$ and $\beta_p$ are obtained by following the same procedures adopted for the magnetization.

**SOME DETAILS ABOUT HEAT-BATH MONTE CARLO SIMULATIONS**

In this section, we describe with some details how the heat-bath Monte Carlo simulations are carried out in our work to evolve the spins. The interesting point here is that the transition occurs for the pair of spins ($\sigma_{i,j}$, $\mu_{i,j}$) and not for single spins since we have coupled lattices. Moreover, this transition does not depend on current spin. So, the transition probabilities of each possible pair: $(+, +)$, $(-, +)$, $(+, -)$, and $(-, -)$ are calculated by

$$p \left[ \sigma_i \rightarrow (\sigma_{i,j}, \mu_{i,j}) \right] = \frac{1}{S} \exp \left[ -E \left( \sigma_{i,j}, \mu_{i,j} \right) \right]$$

with $S = e^{-E(+,+)} + e^{-E(-,+)} + e^{-E(+,-)} + e^{-E(-,-)}$ and

$$E(+,+) = -K \left( \Delta_{i,j} + \Psi_{i,j} \right) - K_4 \Phi_{i,j},$$

$$E(-,+), E(+,-) = K \left( \Delta_{i,j} - \Psi_{i,j} \right) + K_4 \Phi_{i,j},$$

$$E(-,-) = K \left( \Delta_{i,j} + \Psi_{i,j} \right) - K_4 \Phi_{i,j},$$

where

$$\Delta_{i,j} = \sigma_{i+1,j} + \sigma_{i-1,j} + \sigma_{i,j+1} + \sigma_{i,j-1},$$

$$\Psi_{i,j} = \mu_{i+1,j} + \mu_{i-1,j} + \mu_{i,j+1} + \mu_{i,j-1}$$

and

$$\Phi_{i,j} = \sigma_{i+1,j} \mu_{i+1,j} + \sigma_{i-1,j} \mu_{i-1,j} + \sigma_{i,j+1} \mu_{i,j+1} + \sigma_{i,j-1} \mu_{i,j-1}.$$

For the AT model the order parameters correspond to time-dependent magnetization, polarization, as well as, their superior moments, here represented by a general symbol $O$ defined via our MC simulations as an average over all $L^2$ spins and over the different $N_{run}$ runs (different time evolutions):

$$\overline{O}(t) = \frac{1}{N_{run} L^2} \sum_{k=1}^{N_{run}} \sum_{i,j=1}^{L} O_{i,j,k}(t),$$

(28)

where the index $k = 1, ..., N_{run}$ denotes the corresponding run of each simulation. The ordered state is ferromagnetic, with all (or most of) the spins pointing either up or down.

As discussed in the previous section, the lattice’s initial condition to be simulated in our study depends on the scaling relation as follows:

a) Eqs. (12) and (13). To obtain such power laws, the averages are obtained from a set of runs with initially random configurations allowing the direct calculation of the dynamic exponents $\theta_m$ and $\theta_p$. Here, the only requirement is that $\langle m_0 \rangle = \langle p_0 \rangle = 0$. Unfortunately, the huge fluctuations for $P(t)$, even for $N_{run} = 300,000$ runs, prevented us of estimating $\theta_p$ through this method.
b) Eqs. (14) and (15): In order to obtain the same
exponents \( \theta_m \) and \( \theta_p \) we use these alternative equations.
However, in this case, a careful preparation of the initial
order parameters \((m_0, p_0)\) is needed, besides the limit
procedures \(m_0 \to 0\) and \(p_0 \to 0\). Here we used \(N_{\text{run}} = 100,000\) runs.

c) Eqs. (22) and (23): In order to perform the sim-
ulations to obtain the exponents by these power laws,
we used ordered initial states, which means \(m_0 = 1\) and
\(p_0 = 1\). In this particular case the simulations do not
present sensitive fluctuations and for all cases we used
\(N_{\text{run}} = 4,000\) runs.

d) Eqs. (24) and (25): When computing the second
moment of the magnetization or polarization, we used

\[ m = 0 \] (half (randomly choosen) of spins up and the
other half of the spins down) and

\[ \rho \]

we use these alternative equations.

e) Eq. (26): When dealing with Monte Carlo simu-
lations by estimating the best

\[ \lambda \]

parameters obeys the power law behavior of Eq. (22), for
different values of \(\lambda\). Our initial plan was to study the phase transition
points of the AT model via time-dependent MC simu-
lations by estimating the best \(K\) given as input the pa-
parameter \(K^{(\text{min})}\) (inicial value) and run simulations for
different values of \(K\) according to a resolution \(\Delta K\).

We performed this task for the five points in Fig. 4
by taking into account only the magnetization and the analysis was carried out by using an approach developed
in Ref. 11 in the context of generalized statistics. This
tool had also been applied successfully to study multicrit-
ical points, for example, tricritical points 9 and Lifšhitz
point of the ANNNI model 10, Z5 model 12 and also in
models without defined Hamiltonian 16.

Our initial plan was to study the phase transition
points of the AT model via time-dependent MC simu-
lations by estimating the best \(K\) given as input the pa-
rameter \(K^{(\text{min})}\) (inicial value) and run simulations for
different values of \(K\) according to a resolution \(\Delta K\).

In Table I we collect the considered points \((J)\) as well as the four-body coupling constants \((\lambda)\) in the critical line
of the Baxter model. The corresponding coefficients \(K\)
and \(K_4\) for the Ashkin-Teller model, calculated from Eqs.
(2), (3) and (5), are also shown in this table. We choose
five points \(J = 0.4\), Ising model which corresponds to
\(J = \frac{1}{2}\ln(1 + \sqrt{2})\), \(J = 0.5\), \(q = 3\) Potts (TSP) model
and \(q = 4\) Potts (FSP) model corresponding to \(J \to +\infty\).

In Figure 1 we present the critical line of the AT model and illustrate the points to be considered in this study, as well as the perpendicular lines for each point.

In this section we performed some initial simulations
to give more knowledge about the criticality of the AT
model. The theoretical predictions of the critical line are
described by

\[ K_4(K) = -\frac{1}{2}\ln(\sinh(2K)). \] (30)

therefore, let us consider a particular critical point
of this curve, denoted by \((K^{(c)}_4, K_4^{(c)})\), which corre-
sponds to a particular critical coefficient \(J_c\) of the Bax-
ter model, such that \(\lambda_c = -\frac{1}{2}\ln(\sinh(2J_c))\). Hence,
we obtain \(K_4^{(c)} = \frac{1}{2}\tanh^{-1}\left(\frac{\tanh(2J_c)}{\tanh(2K_4^{(c)})}\right)\) and \(K^{(c)} = \frac{1}{2}\sinh^{-1}(\exp(-2K_4^{(c)}))\).

So, the tangent line to the curve \(K_4(K) = -\frac{1}{2}\ln(\sinh(2K))\) passing by for the critical point
\((K^{(c)}, K_4^{(c)})\) is written as:

\[ K_4 = -\coth(2K_4)(K - K_c) - \frac{1}{2}\ln(\sinh(2K_4)), \]

and the perpendicular line to this tangent line, can be
written as:

\[ K_4^\perp = \tanh(2K_c)(K - K_c) - \frac{1}{2}\ln(\sinh(2K_c)). \] (31)

LOCALIZATION OF CRITICAL POINTS:
POWER LAW OPTIMIZATION

Figure 1. Critical line described by equation \(K_4 = -\frac{1}{2}\ln(\sinh(2K))\). The points correspond to \(J = 0.4, J = 0.5, \) Ising model, \(q = 3\) Potts (TSP) model and \(q = 4\) Potts (FSP) model. The perpendicular lines passing through each point are also presented.

So, the tangent line to the curve \(K_4(K) = -\frac{1}{2}\ln(\sinh(2K))\) passing by for the critical point
\((K^{(c)}, K_4^{(c)})\) is written as:

\[ K_4 = -\coth(2K_4)(K - K_c) - \frac{1}{2}\ln(\sinh(2K_4)), \]

and the perpendicular line to this tangent line, can be
written as:

\[ K_4^\perp = \tanh(2K_c)(K - K_c) - \frac{1}{2}\ln(\sinh(2K_c)). \] (31)
n = [(K^{max}) - K^{(min)})/\Delta K], we performed MC simulations and calculated the coefficient of determination, which is given by

\[ r = \frac{\sum_{t=1}^{N_{MC}} (\langle \ln M \rangle - a - b \ln t)^2}{\sum_{t=1}^{N_{MC}} (\langle \ln M \rangle - \langle M \rangle(t))^2} \]

with \[ \langle \ln M \rangle = \langle 1/N_{MC} \rangle \sum_{t=1}^{N_{MC}} \ln M(t), \] and the critical value \( K_c \) corresponds to \( K^{(opt)} = \arg \max_{K \in \{K^{(min)}, K^{(max)}\}} \{ r \} \). The coefficient \( r \) has a very simple explanation: it measures the ratio: (expected variation)/(total variation). The bigger the \( r \), the better the linear fit in log-scale, and therefore, the better the power law which corresponds to the critical parameter except for an order of error \( \Delta K \).

In our simulations we use square lattices of linear sizes \( L = 64, 128, \) and \( 256 \) and the system evolves in contact with a thermal bath in five points on the self-dual critical line of the Ashkin-Teller model by Li et al. \[55\]. In addition, the exponents \( z_m \) and \( z_p \) were estimated for some points on the self-dual critical line of the Ising model \[20\, 47\, 50\], the TSP model \[20\, 37\, 51\, 52\], and the FSP model \[55\, 57\, 63\, 54\]. These last two exponents, as well as the exponents \( \theta_g \) and \( \theta_p \) were calculated for some points on the self-dual critical line of the Ashkin-Teller model by Takano \[56\]. As far as we know, the dynamic critical exponents \( \theta_g \) and \( \theta_p \) were not found yet for the Ashkin-Teller model. It is important to mention that \( \theta_m \) and \( \theta_g \) have not yet been obtained by power law correlations, as well as the exponents \( z_m \) and \( z_p \) which have not yet been studied through the method that mixes initial conditions. Both methods are employed in this paper. On the other hand, for the static exponents, conjectures assert that the ratio \( \beta_m/\nu_m = 1/8 \) for the entire critical line while \( \beta_p/\nu_p \) is not constant as \( J \) increases. Hence, this fact deserves attention and a detailed study.

In our simulations we use square lattices of linear sizes \( L = 64, 128, \) and \( 256 \) and the system evolves in contact with a thermal bath in five points on the self-dual critical line of the AT model. Our estimates for each exponent and the corresponding error are obtained from five independent seeds of \( N_{run} \) runs each one as previously described in Section I. However, since the two sublattices of the model (\( \sigma \) and \( \mu \) are symmetrical, the number of effective bins for the magnetization are doubled. In or-

![Figure 2. Coefficient of determination \( r \) as function of \( K \) walking on the perpendicular line presented in Fig. 1. The maximum occurs at the expected critical points.](image-url)
order to measure the slopes of the power laws described above (in double-log scale) we consider the time interval [150,300] for the dynamic exponents. For the static ones, a more detailed statistical tool was prepared taking into consideration averages over different seeds and geographic variations. In this case the maximal number of MC steps was \(N_{MC} = 10^3\).

The dynamic critical exponents \(\theta_{gm}\) and \(\theta_{gp}\)

The first exponents we calculate are the global persistence exponents \(\theta_{gm}\) and \(\theta_{gp}\) that are achieved when one considers the global persistence probabilities \(G_m(t)\) and \(G_p(t)\), Eqs. (17) and (18), which are defined as the probabilities of the order parameters (magnetization and polarization) not changing their signs up to the time \(t\), at criticality \((\tau = 0)\).

In order to obtain these exponents, one can define the global persistence probability as

\[
G_m(t) = 1 - \sum_{t' = 1}^{t} \rho_m(t')
\]

and

\[
G_p(t) = 1 - \sum_{t' = 1}^{t} \rho_p(t'),
\]

where \(\rho_m(t')\) and \(\rho_p(t')\) are the fractions of samples that have changed the sign of their magnetization and polarization, respectively, for the first time at the instant \(t'\). Here, the simulations are performed for some predefined values of the initial magnetization \(m_0 \ll 1\) and polarization \(p_0 \ll 1\). Hence, a sharp preparation of the initial states is needed to obtain precise values for them. After obtaining the exponents \(\theta_{gm}\) and \(\theta_{gp}\) for each value of \(m_0\) and \(p_0\), respectively, the final values are achieved by performing the limit procedures \(m_0 \to 0\) and \(p_0 \to 0\).

In this paper, we consider the following values for \(m_0\) and \(p_0\): 0.002, 0.004, 0.006, and 0.008. To obtain these values, we first insert randomly, at each site of the sublattices, a spin variable that takes the values \(\pm 1\). After that, the magnetization of the sublattices and the polarization of the system are measured by using Eq. (3). Then, spin variables are chosen randomly and their sign are changed until we obtain a null value for the magnetizations and polarization. The last procedure is to change the signs of \(\delta/2\) sites of each sublattice, at random, to obtain the desired initial magnetization \(m_0\) and polarization \(p_0\).

In Fig. 3 we show the decay of the global persistence probability of the magnetization (on top) for the five considered points, for \(L = 256\) and \(m_0 = 0.008\). The error bars are smaller than the symbols. In that same figure, at the bottom, we present the plots of \(\theta_{gm}\) as function of \(m_0\), as well as the limit procedure \(m_0 \to 0\).

Figure 3. Global persistence probability of the magnetization for \(L = 256\). On top, polynomial decay of \(G_m(t) \times t\) for \(m_0 = 0.008\). At the bottom, linear fit of the estimates obtained for different values of \(m_0\).

Table II presents the results obtained from the limit procedure for the three lattices, \(L = 64, 128,\) and \(256\).

| \(J\)  | \(L = 64\) | \(L = 128\) | \(L = 256\) |
|-------|-----------|-----------|-----------|
| 0.4   | 0.2086(19)| 0.2211(16)| 0.2283(28)|
| 0.5   | 0.2417(25)| 0.2656(7) | 0.2618(14)|
| TSP   | 0.2835(18)| 0.3032(20)| 0.3089(23)|
| FSP   | 0.4678(38)| 0.4763(60)| 0.4679(13)|

Table II. The global persistence exponent \(\theta_{gm}\) for the five considered points.

The results show that the dynamic critical exponent \(\theta_{gm}\) grows monotonically with \(J\). Moreover, the values obtained for the Ising, TSP, and FSP models can be compared with results obtained previously and found in literature.

For the Ising critical point, the uncoupled point, our result is in complete agreement with that presented by Schulke et al. [24], \(\theta_g = 0.238(3)\). Our result can also be
compared to the value obtained by Majumdar et al. [22] using a finite-size scaling technique. By starting from a random initial configuration and collapsing the data, they found $\theta_g z = 0.505(20)$. If we consider our estimate for $z_m$ (presented in Section 1), $z_m = 2.156(11)$, one finds $\theta_g = 0.234(10)$. This result is slightly smaller than the value obtained in this paper but it is in agreement with each other when considering the statistical errors.

For the TSP critical point, our result should be compared to the value $\theta_g = 0.350(1)$ also obtained in Ref. [24]. This estimate is larger than ours even when one considers the statistical errors. Then, as occurs with other models and exponents, maybe further studies are needed in order to allow a comparison of the results.

For the FSP model, Fernandes et al. [23] obtained $\theta_g = 0.474(7)$ and Arashiro et al. [21] found $\theta_g = 0.475(5)$ for the FSP model and $\theta_g = 0.471(5)$ for the $n = 3$ Turban model (this model belongs to the $q = 4$ Potts model universality class.) Therefore, our estimate is in good agreement with those ones obtained previously.

Fig. 4 shows the global persistence probability in double-log scale for the polarization, for the five points along the self-dual critical line (on top), $L = 256$ and $p_0 = 0.008$. The error bars are smaller than the symbols. The plots of $\theta_{gp}$ as function of $p_0$, as well as the limit procedure $p_0 \rightarrow 0$ are shown at the bottom of this figure and the extrapolated values are presented in Table III.

Table III. The global persistence exponent $\theta_{gp}$ for the five considered points.

| $J$ | $L = 64$ | $L = 128$ | $L = 256$ |
|-----|----------|-----------|-----------|
| 0.4 | 1.143(55)| 1.035(12) | 1.044(19) |
| Ising model | 0.9941(76)| 0.9867(57)| 1.0027(80) |
| 0.5 | 0.9279(186)| 0.9186(114)| 0.9137(346) |
| TSP model | 0.8183(224)| 0.7988(94)| 0.777(121) |
| FSP model | 0.4607(105)| 0.4570(106)| 0.4741(108) |

For the polarization, the global persistence exponent decreases monotonically with $J$ showing, as above, the nonuniversal character of the model. The values of the exponent are higher than for $\theta_{gm}$ but this difference disappears for the $q = 4$ Potts critical point whereas in this point $K = K_4$ and both $\theta_{gm}$ and $\theta_{gp}$ share the same value.

### Dynamic critical exponents $\theta_m$ and $\theta_p$

As stressed before, we consider two different approaches to estimate the exponents $\theta_m$ and $\theta_p$. Our first attempt is related to the time correlation of the magnetization and polarization, Eqs. (12) and (13), respectively. However, the huge fluctuations, even for 300,000 samples, prevented us of considering this technique to obtain $\theta_p$. In Fig. 5 $Q_M(t)$ is plotted in double-log scale for five different values of $J$.

Table IV. The dynamic critical exponent $\theta_m$ obtained from the time correlation of the magnetization, $Q_M(t)$, for the five coupling constants of the Baxter model at the self-dual critical line of the Ashkin-Teller model.

For the second method consists of calculating the exponents $\theta_m$ and $\theta_p$ for different values of $m_0 \ll 0$ and $p_0 \ll 0$, respectively, by using the Eqs. (14) and (15). Their final values are then obtained by carrying out the limit procedure $m_0 \rightarrow 0$ and $p_0 \rightarrow 0$. In order to avoid huge fluctuations of the order parameters, which arise when $m_0$ and $p_0$ are very close to zero, we consider the

![Figure 4. Global persistence probability of the polarization for $L = 256$. On top: polynomial decay of $G_p(t) \times t$ for $p_0 = 0.008$. At the bottom: linear fit of the estimates obtained for different values of $p_0$.](image-url)

![Figure 5. Plot of $Q_M(t)$ in double-log scale for five different values of $J$.](image-url)
following values of \( m_0 \) and \( p_0 \): 0.02, 0.04, 0.06, and 0.08.

Fig. 6 shows the polynomial behavior of \( M(t) \times t \) for \( m_0 = 0.06 \) in double-log scales, for the five different values of \( J \) and \( L = 256 \) (on top).

The limit procedures are shown at the bottom of this figure and the extrapolated values can be seen in Table V for the three lattices, \( L = 64, 128, \) and 256.

| \( J \) | \( L = 64 \) | \( L = 128 \) | \( L = 256 \) |
|---|---|---|---|
| 0.4 | 0.2171(23) | 0.2198(35) | 0.2203(45) |
| Ising model | 0.1915(16) | 0.1999(20) | 0.2015(26) |
| 0.5 | 0.1681(64) | 0.1646(33) | 0.1666(14) |
| TSP model | 0.1172(19) | 0.1196(9) | 0.1176(10) |
| FSP model | -0.0580(21) | -0.0707(59) | -0.0611(42) |

Table V. The dynamic critical exponent \( \theta_m \) for the five considered points.

Our results displayed in Tables IV and V are in good agreement with each other and show that the exponent \( \theta_m \) varies continuously with \( J \). The estimates also corroborate the available values for the Ising and FSP models. For the former one, our results should be compared with those showed by Grassberger [50], \( \theta = 0.191(3) \), Li et al. [55], \( \theta = 0.191(2) \), and Okano et al. [49], \( \theta = 0.191(1) \).

For the FSP model, Okano et al. [49] conjectured that the exponent \( \theta \) should be negative and close to zero and the results for this model [55] as well as for the Ising model with three-spin interactions [54] validate this assertion. Besides the \( q = 4 \) Potts model, there have been shown in some papers that there are models in which the exponent \( \theta \) can also have a negative value, for instance, the tricritical Ising model [58], Blume-Capel model [38], metamagnetic model [39], and Baxter-Wu model [48, 59].

On the other hand, our estimate for the TSP model is completely different from some values published up to now, 0.0815(27) [51] and 0.075(3) [60]. Nevertheless, our estimate, is in agreement with the result for the same point in the critical self-dual line of the Ashkin-Teller model [55]. In that work, the authors do not estimate directly the exponent \( \theta_m \) for the critical point of the TSP model \( (y = 3/4) \). However, as pointed out by Chatelain [52], this exponent varies roughly linearly with the parameter \( y \) which allows us to estimate the exponent \( \theta_m \) in this point, leading to \( \theta_m \approx 0.111 \). This result is compatible with ours for the critical point of the TSP model.

In order to obtain the exponent \( \theta_p \), we first consider the same initial conditions, i.e., \( p_0 = 0.02, 0.04, 0.06 \) and 0.08. Fig. 7 displays the behavior of \( P(t) \times t \), Eq. (15), in double-log scale for \( p_0 = 0.08 \) and \( L = 256 \) for the five critical points considered. The extrapolated values, obtained from the limit procedure \( p_0 \to 0 \), are presented in Table VI for the three lattices, \( L = 64, 128, \) and 256.

The results show that the exponent \( \theta_p \) decreases monotonically with respect to \( J \). They are completely different from those obtained by Li et al. [55], but for the \( q = 4 \)
The dynamic critical exponent $z_m$ and $\nu_p$

Finally, the dynamic critical exponents $z_m$ and $\nu_p$ are obtained by combining results from samples submitted to different initial conditions (ordered state for the order parameter and disordered one for the second moment of the order parameter), Eqs. (20) and (21), where the dimension of the system is $d = 2$. This technique has proven to be very efficient in estimating the exponent $z$ for a large number of models [35, 37, 38, 43, 44, 54].

The time evolution of $F_{2M}$, obtained from Eq. (20), is shown in Fig. 8 in double-log scale for the five considered points and $L = 256$. The error bars are smaller than the symbols.

![Figure 7. The plot of $P(t) \times t$, Eq. (15), for the initial polarization $p_0 = 0.08$ and $L = 256$. On top: polynomial behavior of $P(t) \times t$. At the bottom: linear fitting of the estimates obtained for different values of $p_0$.](image1)

![Figure 8. Time evolution of $F_{2M}(t)$ for the five coupling constants and $L = 256$.](image2)

Table VI. The dynamic critical exponent $\theta_p$ for the five considered points.

| $J$   | $L = 64$     | $L = 128$   | $L = 256$   |
|-------|---------------|-------------|-------------|
| 0.4   | 0.4466(320)   | 0.4364(16)  | 0.4301(7)   |
| Ising model | 0.4317(39)  | 0.3857(94)  | 0.3638(58)  |
| 0.5   | 0.2797(361)   | 0.3017(125) | 0.2860(115) |
| TSP model | 0.1403(372)  | 0.0937(210) | 0.1106(59)  |
| FSP model | -0.0611(115) | -0.0597(44) | -0.0645(1)  |

Potts critical point ($y = 1$ in that paper). They showed that the polarization is negative for all considered points.

The mean values of $z_m$ and the corresponding errors are given in Table VII for $L = 64, 128$, and 256.

Table VII. The dynamic critical exponent $z_m$ for the five considered points.

| $J$   | $L = 64$ | $L = 128$ | $L = 256$ |
|-------|----------|----------|----------|
| 0.4   | 2.113(18) | 2.139(16) | 2.147(12) |
| Ising model | 2.129(12) | 2.156(11) | 2.156(11) |
| 0.5   | 2.154(9)  | 2.168(13) | 2.172(13) |
| TSP model | 2.175(5)  | 2.198(14) | 2.194(17) |
| FSP model | 2.318(11) | 2.342(21) | 2.346(21) |

In the uncoupling point, $J = K = 0.5\ln(1 + \sqrt{2})$, the exponent $z_m$, is in complete agreement with those obtained for the two-dimensional Ising model [48, 49]. For the TSP model, our estimate is also in complete agreement with those ones presently accepted for the model, $z = 2.1983(81)$ [51], obtained from the time evolution of the self-correlation and $z = 2.197(3)$ obtained by mixing moments of the magnetization under different initial conditions [37], $F_2(t)$. However, our estimate of $z_m$ for the FSP model, is larger, but very close to the values recently obtained for that model, $z = 2.290(3)$ [37] and $z = 2.294(3)$ [35], for the Baxter-Wu model [43], $z = 2.294(6)$, and for the $n = 3$ Turban model [51], $z = 2.292(4)$, both belonging to the same universality class of the FSP model.
In the previous section, we calculate the exponent analysis of uncertainties and of final estimates. In this computing of static exponents deserve a more detailed distinction between the two critical indexes. On the contrary, the exponent is greater than for the five coupling constants.

The linear fits of these curves, as well as of those ones with $L = 64$ and $L = 128$, lead to the values presented in Table VIII.

| $J$ | $L = 64$     | $L = 128$    | $L = 256$     |
|-----|--------------|--------------|--------------|
| 0.4 | 1.889(19)    | 2.236(16)    | 2.201(8)     |
| IIsing model | 1.932(25)    | 2.225(21)    | 2.220(16)    |
| 0.5 | 2.004(25)    | 2.232(17)    | 2.212(26)    |
| $q = 3$ Potts model | 2.092(10)    | 2.253(19)    | 2.258(17)    |
| $q = 4$ Potts model | 2.210(12)    | 2.341(12)    | 2.338(38)    |

Table VIII. The dynamic critical exponent $z_p$ for the five considered points.

By taking into account the statistical errors, the results shown in Tables VII and VIII ensure that the exponents $z_m$ and $z_p$ are varying with respect to $J$. In this case, only the exponent for FSP model is different from the others. Besides, for this critical point, the exponents $z_m$ and $z_p$ share the same values (within the error bars). On the contrary, the exponent $z_p$ is greater than $z_m$ for the other points, in contrast with the results shown in Ref. 55 for the Ashkin-Teller model, where there is no distinction between the two critical indexes.

**Static critical exponents**

Here we finally calculate the static critical exponents of de AT model. By using the exponents $z_m$ and $z_p$ obtained in the previous section, we calculate the exponent $\nu$ for the magnetization and polarization respectively. Differently from what occurs with the dynamic exponents, the computing of static exponents deserve a more detailed analysis of uncertainties and of final estimates. In this analysis we consider both the external and internal averages.

In this paper, the static exponents were calculated by using $N_{run} = 4000$ runs in order to compute the averaged time series in the situation which the system starts from $m_0 = 1$ (or $p_0 = 1$). First, the error bars are obtained with $N_0 = 5$ different bins (for polarization). For the case of magnetization we have $N_0 = 10$ different bins since the lattices are doubled. Here it is important to differentiate “bin” of “seed”. We always used 5 seeds, but due to duplication of lattices in the AT model, and considering the isotropic case ($K_1 = K_2 = K$) the number of bins is equal to the double of seeds for the magnetization case.

We numerically compute the derivative through Eqs. (26) and (27), which leads to:

$$D(t) = \frac{1}{2\delta} \frac{\tilde{O}(K_4(T_c + \varepsilon), K(T_c + \varepsilon), t)}{\tilde{O}(K_4(T_c - \varepsilon), K(T_c - \varepsilon), t)}$$

where $\tilde{O}(K_4(T), K(T), t)$ denotes the averaged magnetization/polarization calculated in values above and below the critical temperatures. If $K(T_c) = K_c = \frac{1}{T_c}$ it is interesting to observe that a perturbation on the critical temperature, $T_c \pm \varepsilon$, produces $K(T_c \pm \varepsilon) = 1/(T_c \pm \varepsilon) = (1/\varepsilon/T_c) = K_c/(1 + \delta)$, where $\delta = \varepsilon/T_c$. This means that when we divide $K_c$ by $(1 + \delta)$, the critical temperature is perturbed by a value $\pm \varepsilon = \pm \delta T_c$. Similarly, $K_4(T_c \pm \varepsilon) = K_4/(1 \pm \delta)$.

Fig. 10 shows the time evolution of $D(t)$ for magnetization and polarization, calculated by Eq. (35). For the magnetization, the error bars are obtained by using an average over different $N_b^2 = 100$ points while for the polarization $N_b^2 = 25$ points since we cross the time series simulated above critical parameter: $\tilde{O}(T_c + \varepsilon, t)$, on the perpendicular line as previously described, with $N_b$ time series simulated below critical parameter $\tilde{O}(T_c - \varepsilon, t)$. We can clearly observe a power law behavior (log-log plot) for all points studied.

So, in order to compute the static exponents, we observe that the exponent $\phi = 1/(\nu z)$ has an important variation on the different time lags considered, and therefore, such a variation must be considered in the final estimates of the exponent $\nu$. In this analysis we index by $k$ the time lag $[t_i^{(k)}, t_f^{(k)}]$, where $k = 1, ..., n$. It was built considering that the minimum size of the interval is $\Delta = 100$ MCsteps. Moreover, the minimum $t_i$ adopted is 50 MCsteps, while the maximum $t_f$ is 1000 MCsteps.

We prepared an algorithm that considers the same number of points per interval which allows to perform linear fits under the same conditions for all different intervals considered in the analysis. The appropriate number of points per interval in this paper was $n_y = 25$, and the spacing was adjusted to satisfy such restriction.

Let us denote here: $\tilde{O}_j(T_c + \varepsilon, t)$ the order parameter averaged over $N_{run}$ different runs corresponding to the
which is an average over the time lags and which leads to a final uncertainty:

\[
\sigma_\phi^2 = \frac{1}{n(n-1)} \sum_{k=1}^{n} (\phi_k - \bar{\phi})^2 + \frac{1}{n} \sum_{k=1}^{n} \sigma_k^2
\]

\[
= \sigma_{\text{ext}}^2 + \sigma_{\text{int}}^2
\]

where the first term of the right side corresponds to external uncertainty (variation over the time lags). This term is a kind of geographic variation of the exponent. The second part corresponds to the internal component of uncertainty, i.e., the variation over the pairs of the different seeds for each time lag. For the more skeptical, we also elaborate a bootstrapping version of this analysis. In this case we choose two sets of 5 seeds (which should be repeated as prescribed by the bootstrapping method) and compose two new time series by averaging them. The first one corresponding to the parameter \( T_c + \varepsilon \) and the other one corresponding to the parameter \( T_c - \varepsilon \) yields an exponent. We can repeat this procedure \( N_{\text{sample}} \) times instead of taking the \( N_{\text{sample}}^2 \) possible pairs. So we can replace the Eqs. (36) and (37) by:

\[
\phi_k = \frac{1}{N_{\text{sample}}} \sum_{i=1}^{N_{\text{sample}}} \phi_{k(i)}
\]

and

\[
\sigma_k^2 = \frac{1}{(N_{\text{sample}} - 1)} \sum_{i=1}^{N_{\text{sample}}} (\phi_{k(i)} - \phi_k)^2
\]

where \( \phi_{k(i)} \) denotes the exponent calculated for the \( i \)-th element of the sample for the \( k \)-th time lag. The Eq. (38) remains the same. Given the exponent \( z \pm \sigma_z \) previously calculated, the final estimate of \( \nu \) is obtained as \( \nu = (z\phi)^{-1} \), and the uncertainty is obtained by

\[
\sigma_\nu = \nu \sqrt{\left( \frac{\sigma_z}{z} \right)^2 + \left( \frac{\sigma_\phi}{\phi} \right)^2}
\]

First of all, in order to observe the variation of the exponent \( \nu \) over the different time lags we prepare a plot to show the variation of \( \nu \) and its respective error bars for the different parts (time lags) of the power law (Fig. 11). The \( x \)-axis denotes a number that indexes one specific time lag. It is important to mention that, it is a simple ordering whereas we do not know which time lag corresponds to the specific exponent since we are interested only in observing the fluctuations of this exponent. In this figure, we show the exponents of the magnetization for the points corresponding to: Ising model, TSP, and FSP models where the right side corresponds to estimates obtained by using bootstrapping and the left side the regular method (both previously described).

This plot shows that the estimates can be deeply changed along the power law but the theoretical prediction is corroborated. The bootstrapping method produces higher error bars as expected. So, taking into account the different source variations, we obtain estimates to the exponent \( \nu \) for the different points studied in this paper. In Table [IX] we present our final estimates of this exponent. The term (boot) refers to estimates obtained using bootstrapping. The terms \( \text{max} \) and \( \text{min} \) mean the largest and smallest values found in our analysis. The conjectured values are shown in the las column and denoted by an asterisk, and are expected to share the same
Figure 11. Estimates of the exponents $\nu_m$ for the different time lags. The left-side plots show the exponents obtained by bootstrapping method by adopting $N_{\text{sample}} = 10^3$ while the right-side ones were obtained with a simple crossing of $N_b = 10$ seeds (100 points).
value for both magnetization ($m$) and polarization ($p$). We can observe a good agreement between the conjectured values and our estimates.

It is important to mention that it is the first time that such exponents have been obtained by MC simulations and to the best of our knowledge, even for equilibrium MC simulations. The agreement between the exponents $\nu$ for the polarization and magnetization was only a conjecture.

By following the same process, we analyze the decay of magnetization and polarization described by Eqs. (22) and (23). The time evolving of these amounts are shown in Fig. 12.

Here we proceed exactly as before to calculate $\beta$. We analyze the external (over different time lags) and internal (over different bins) variations to estimate the exponent $\mu = \beta/(\nu z)$. After a final estimate of $\mu$ and with the previous estimates of $\nu$ and $z$, we obtain an uncertainty for $\beta$: $\sigma_\beta^2 = \beta^2 \left[ \left( \frac{\sigma_\nu}{\nu} \right)^2 + \left( \frac{\sigma_z}{z} \right)^2 + \left( \frac{\sigma_\nu}{\nu} \right)^2 \right]$. We present our estimates of $\beta$ in Table IX as we did for $\nu$ in Table IX.

Differently from what happens for $\nu$ (Table IX), the conjectured values of $\beta$, for magnetization and polarization, are different and our simulations corroborate both values. It is important to notice that the exponents are the same for the FSP point. In order to test the consistency of the estimates for $\beta$ and $\nu$ we can compare $\beta/\nu$ with conjectured values (see, for example, Ref. [61]). It is important to stress that $\beta$ and $\nu$ may not be the same used in other papers and a comparison must be done with some care.

**Figure 12.** Time evolving of $M(t)$ (on the top) and $P(t)$ (on the bottom), for $m_0 = 1$ (or $p_0 = 1$) for the five coupling constants.

**Figure 13.** The ratio $\beta/\nu$ calculate for magnetization (on the top) and polarization (on the bottom). Our values present an excellent agreement with the conjecture.
with our time-dependent Monte Carlo simulations, i.e., the exponents can be obtained even out of equilibrium extending even more the applicability of this wide and successful approach.

### CONCLUSION

In this paper, we studied the non-equilibrium critical behavior of the Ashkin-Teller model by performing Monte Carlo simulations far from equilibrium. The dynamic critical exponents \( \theta_p, \theta, \) and \( z \) were obtained for the two order parameters of the model: the magnetization and polarization. The simulations were carried out on five different points on the self-dual critical line including the Ising, \( q = 3 \) and \( q = 4 \) Potts critical points. The exponents obtained on these points, for the magnetization, are in good agreement when compared with available values in the literature except for the exponent \( z_m \) for the \( q = 4 \) Potts critical point that is slightly larger than that found in literature as well as the exponent \( \theta_{gm} \) for the \( q = 3 \) Potts critical point. We also found for this critical point an exponent \( \theta_m \) larger than those presented in literature. Even with the Chatelain’s argument [52], we think that further study is needed to explain this difference in the exponents \( \theta_{gm} \) and \( \theta_m \) of the model. Besides, as stated by Li et al. [55] and Takano [60], when studying the Ashkin-Teller and Baxter models, respectively, the exponents \( z_m \) and \( z_p \) are almost constant but for the \( q = 4 \) Potts critical point.

We also obtained the static exponents. Our results after a careful method to obtain the exponents presented a good agreement with conjectured results from literature. The ratio \( \beta/\nu \) decreases when \( J \) increases for the polarization but remains the same (according to our error bars) for the magnetization.

In this work, we showed again the wide applicability of the theory of short time dynamics to describe critical phenomena retrieving equilibrium parameters in simulations out of equilibrium as well as predicting nonequilibrium critical indexes. As an important additional contribution, we also proposed a statistical approach to estimate exponents in time-dependent MC simulations by composing fluctuations from intra and inter time-lags to produce suitable error bars.
