Abstract
Magnetohydrodynamic (MHD) shocks are violent events that inject large amounts of energy in the interstellar medium dramatically modifying its physical properties and chemical composition. Indirect evidence for the presence of such shocks has been reported from the especial chemistry detected toward a variety of astrophysical shocked environments. However, the internal physical structure of these shocks remains unresolved since their expected spatial scales are too small to be measured with current instrumentation. Here we report the first detection of a fully spatially resolved, MHD shock toward the infrared dark cloud (IRDC) G034.77-00.55. The shock, probed by silicon monoxide (SiO) and observed with the Atacama Large Millimeter/submillimeter Array (ALMA), is associated with the collision between the dense molecular gas of the cloud and a molecular gas flow pushed toward the IRDC by the nearby supernova remnant (SNR) W44. The interaction is occurring on subparsec spatial scales thanks to the enhanced magnetic field of the SNR, making the dissipation region of the MHD shock large enough to be resolved with ALMA. Our observations suggest that molecular flow–flow collisions can be triggered by stellar feedback, inducing shocked molecular gas densities compatible with those required for massive star formation.

Key words: ISM: clouds (G034.77-00.55) – ISM: molecules – ISM: supernova remnants (W44) – shock waves

1. Introduction
Interstellar magnetohydrodynamic (MHD) shocks are known to exist in a wide variety of astrophysical environments such as jets and molecular outflows (Martín-Pintado et al. 1992; Caselli et al. 1997; Girart & Acord 2001), stellar winds (Wilkin 1996; Babel & Montmerle 1997), and supernovae explosions (Gottelf et al. 2001; Grefenstette et al. 2014; Miceli et al. 2019). Depending on the propagation speed, pre-shock gas density, and magnetic field strength, MHD shocks can be either J type (from jump; fast shocks with \( v_s \geq 45-50 \text{ km s}^{-1} \) and with a discontinuity in the gas physical properties) or C type (more gentle interactions found in molecular clouds with low-ionization fractions, where the gas physical properties change in a continuous manner; Draine 1980; Draine et al. 1983; Neufeld & Dalgarno 1989). If the MHD shock has not attained the steady state, theory predicts the presence of a J-type discontinuity within the structure of the shock at the early stages of its propagation (the piston), which later on evolves into a C-type shock (a nonstationary CJ-type shock; Chiéze et al. 1998; Flower & Pineau de Forêts 2003; Lesaffre et al. 2004).

In star-forming regions, MHD shocks are expected to develop across spatial scales of \( 10^{14} - 10^{15} \text{ cm} \) (\( 0.05" - 0.5" \) at a distance of 140 pc; Gusdorf et al. 2008), too small to be easily resolved with current instrumentation. However, interstellar shocks are also predicted to arise when large-scale flows of molecular gas are pushed to collide. In such collisions, the shock occurs across parsec/subparsec spatial scales (\( 3 \times 10^{17} - 3 \times 10^{18} \text{ cm} \)), sufficient to spatially resolve its physical and dynamical evolution (Inutsuka et al. 2015; Wu et al. 2015).

In this Letter, we report the first images of the internal physical structure of a nonstationary CJ-type shock. The emission of the typical shock tracer SiO has been mapped with Atacama Large Millimeter/submillimeter Array (ALMA) toward the IRDC G034.77-00.55 (hereafter G034), which is located at 2.9 kpc in a highly dynamical environment between the H II region G034.8-00.7 and the supernova remnant (SNR) W44. The interaction between G034 and W44, located at the same distance, has long been established (e.g., Claussen et al. 1997; Seta et al. 1998, 2004; Ortega et al. 2007; Yoshiike et al. 2013; Ranasinghe & Leahy 2018), making G034 an ideal target for MHD shock investigation. Our ALMA images show that a molecular gas flow pushed by the expanding shell of W44 is interacting with a dense molecular ridge in G034 forcing the molecular flow to decelerate and plunge onto the infrared dark cloud (IRDC). This interaction enhances the density of the gas in the ridge to levels required for the formation of the most massive stars.
2. Observations

We used ALMA Band 3 during Cycle 4 (PI: I. Jimenez-Serra) to map the SiO $J = 2 \rightarrow 1$ transition (86.85 GHz) toward G034. Observations were performed using the ALMA Compact Array (11 antennas) plus 45 antennas of the 12 m array (baseline 15–331 m; uv distance 4.3–9.6 kλ). Observations were performed in dual polarization mode, using a spectral bandwidth of 58.594 MHz. The sources J1751+0939 and J1851+0035 were used as calibrators. We reproduced the two calibrated data sets by running the original pipeline reduction scripts and used the task aimage in CASA version 4.7.212 to subtract the continuum emission previously estimated from line-free channels. The two continuum-subtracted data cubes were combined using the task concat. We generated the SiO line-only final image using the task clean with Briggs weighting (robust parameter 0.5), phase center $\alpha(J2000) = 18^\mathrm{h}56^\mathrm{m}4^\mathrm{s}7^\prime$, $\delta(J2000) = 1^\circ23^\prime25^\prime$, and velocity resolution 0.1 km s$^{-1}$ ($\sim$30 kHz). The final high angular resolution images have a synthesized beam of $3^{\prime\prime}5 \times 2^{\prime\prime}5$, position angle (PA) = $84^{\circ}27^\prime$, and noise level of 10 mJy beam$^{-1}$. By comparing the ALMA and IRAM 30 m spectra extracted toward the position of the SiO peak detected by Cosentino et al. (2018) in this cloud, we find that no significant flux is missing in the 12 m+ACA SiO image. The 3 mm continuum map obtained with the 12 m array does not show any continuum pointlike source spatially associated with SiO and above the 3σ level ($1\sigma = 66\mu$Jy beam$^{-1}$).

Observations of the C$^{18}$O $J = 1 \rightarrow 0$ (109.78 GHz) and $J = 2 \rightarrow 1$ (219.56 GHz) lines were carried out with the IRAM 30 m telescope in 2012 July. The On-The-Fly maps were obtained using the offset position ($-240^\prime$, $-40^\prime$) and a dump speed of 6.0 s$^{-1}$. Pointing accuracy was $\leqslant 3^\prime$ and line calibrations were performed on the source G34.4+0.3. The fast Fourier Transform Spectrometer (FTS; 4 GHz full bandwidth) provided a spectral resolution of 200 kHz, i.e., 0.54 km s$^{-1}$ at 109.78 GHz and 0.27 km s$^{-1}$ at 219.56 GHz.

The final data cubes, created using the CLASS software within GILDAS,13 have a spatial resolution and beam efficiency of 24$^\prime$ and 0.78 for C$^{18}$O(1–0) and 12$^\prime$ and 0.63 for C$^{18}$O(2–1). The final rms is 0.1 K for both spectra.

3. Results

3.1. SiO ALMA Data: Moment Maps and Position–Velocity (PV) Diagrams

In Figure 1, we present the three-color image of G034 (black circle) located between W44 (blue circle) and the H II region G034.758-00.681 (green circle). Red is 24 μm emission (Spitzer MIPS; Carey et al. 2009), green is 8 μm emission (Spitzer GLIMPSE; Churchwell et al. 2009), and blue shows a combined Jansky Very Large Array (JLVA) and Green Bank Telescope (GBT) 21 cm continuum map (THOR survey; Beuther et al. 2016). The white square indicates the ALMA mosaic area and the gray shadow corresponds to $A_v \geq 20$ mag.

Figure 1. Three-color image of G034 showing its position (black circle) between W44 (blue circle) and G034.758–00.681 (green circle). Red is 24 μm emission (Spitzer MIPS; Carey et al. 2009), green is 8 μm emission (Spitzer GLIMPSE; Churchwell et al. 2009), and blue shows a combined JLVA+GBT 21 cm continuum map (THOR survey; Beuther et al. 2016). The white square indicates the ALMA mosaic area and the gray shadow corresponds to $A_v \geq 20$ mag.

$v_{LSR} \sim 45$–50 km s$^{-1}$ (i.e., distances $S \geq 1$ in Figures 6 and 7 of Sashida et al. 2013).

Figure 2 reports the integrated intensity map (black contours; velocity range 36.6–47.6 km s$^{-1}$) and the velocity moment 1 map (red scale) of the SiO emission measured toward G034 with ALMA. These maps appear superimposed on the $A_v = 20$ mag visual extinction level of the cloud (Kainulainen & Tan 2013), which shows a dense ridge toward the northwest of G034. The SiO emission is organized into two plane-parallel structures: a bright elongation peaking outside the ridge at redshifted velocities with respect to the radial velocity of the IRDC ($v_{LSR} = 43$ km s$^{-1}$) and a fainter elongation found into the ridge between $\sim$36–42 km s$^{-1}$. The SiO channel maps (Figure 3) reveal that shifting from 46 to 39 km s$^{-1}$, SiO first appears in a region outside the $A_v \sim 20$ mag ridge, to progressively move toward the cloud bending and spreading onto it (as if it had impacted).

To analyze the velocity structure of the SiO shocked gas, we have extracted PV diagrams along two representative directions perpendicular to the observed SiO elongations, PV north and PV south (blue arrows in Figure 2). Figure 4 shows that the deceleration of the gas is occurring in two steps: a first almost vertical velocity decrease of $\sim$2–3 km s$^{-1}$ within a spatial width lower than the angular resolution ($\leqslant 2^\prime$5), and a second and shallower deceleration of $\sim$4–5 km s$^{-1}$ measured across $\sim$10–20$^\prime$. This resembles the predicted velocity structure of CJ-type shocks (Section 4 and Chièze et al. 1998; Lesaffre et al. 2004). The comparison between the SiO PV diagrams and the visual extinction profiles of G034 along the PV directions reveals that the observed SiO spatially coincides with extinction peaks across the ridge (bottom brown curves in Figure 4). This is consistent with the idea that the two shocked plane-parallel structures (probed by SiO) appear once the molecular gas expanding from W44 encounters the high-density wall of the ridge.
3.2. C18O Single-dish Spectra: H2 Density and SiO Abundance Enhancement in the Post-shock Gas

Figure 5 shows spectra of C18O (1–0) (black) and C18O (2–1) (blue) measured over a 25" beam toward two positions in G034, one outside and one inside the ridge (magenta circles in Figure 2). Outside the ridge, where no SiO is detected, only the quiescent (pre-shock) component at ~43 km s\(^{-1}\) can be seen (Figure 2, bottom panel). However, inside the ridge, a second component at ~40 km s\(^{-1}\) clearly appears coinciding with the detection of SiO (the post-shock gas; top panel).

By using the radiative transfer code RADEX (Van der Tak et al. 2007), we can infer the H2 gas volume density of the pre-shock (~43 km s\(^{-1}\)) and post-shock (~40 km s\(^{-1}\)) gas in G034 from the C18O J = 1 → 0 and J = 2 → 1 emission. We assume a kinetic temperature of 15 K (typical of IRDCs; Pillai et al. 2007) and mean line width of 2 km s\(^{-1}\). The physical properties of the pre-shock gas at 43 km s\(^{-1}\) are \(n(H_2) \sim 10^5\) cm\(^{-3}\), \(N(C^{18}O) \sim 1.8 \times 10^{13}\) cm\(^{-2}\), \(\tau \sim 0.17\), and Tex \(\sim 9\) K, while for the post-shock gas at 40 km s\(^{-1}\) the inferred values are \(n(H_2) > 10^6\) cm\(^{-3}\), \(N(C^{18}O) \sim 9 \times 10^{14}\) cm\(^{-2}\), \(\tau \sim 0.36\), and Tex \(\sim 7\) K. Hence, the density of the post-shock gas is a factor of \(>10\) higher than the density of the pre-shock gas. Note that the estimated excitation temperatures are comparable to those reported in Cosentino et al. (2018) for CH3OH, another shock tracer.

We also estimate the SiO total column density, \(N(\text{SiO})\), for the pre-shock (~43 km s\(^{-1}\)) and post-shock (~40 km s\(^{-1}\)) gas. Since no SiO emission is present outside the ridge, the 3\(\sigma\) upper limit for \(N(\text{SiO})\) in the pre-shock gas is \(6 \times 10^9\) cm\(^{-2}\) by considering an rms noise level of 10 mJy beam\(^{-1}\). For the post-shock gas, the derived \(N(\text{SiO})\) is \(1.6 \times 10^{12}\) cm\(^{-2}\). Hence, the abundance of SiO has been enhanced by a factor \(>500\) in the post-shock gas in G034, as inferred from the \(N(\text{SiO})/N(C^{18}O)\) column density ratios.

3.3. 3 mm Continuum Emission

From the 3\(\sigma\) rms level measured in our ALMA 3 mm continuum image (0.2 mJy), we can estimate an upper limit to the envelope mass of any possible protostar present in the region as

\[
M_{env} = \frac{F_d d^2}{B_k k_v M_{dust}} \frac{M_{gas}}{M_{dust}},
\]

where \(F_d\) is the continuum flux, \(d\) is the source distance, \(k_v\) is the dust opacity, \(B_k(T_{dust})\) is the Planck function at the dust temperature \(T_{dust}\), and \(M_{gas}/M_{dust}\) is the gas-to-dust mass ratio (Ossenkopf & Henning 1994). We assume \(d = 2.9\) kpc, \(T_{dust} = 15\) K, \(M_{gas}/M_{dust} = 100\), and \(F_d = 0.2\) mJy. Dust opacity at 3 mm is extrapolated to \(k_v = 0.0237\) m\(^2\) kg\(^{-1}\) (Ossenkopf & Henning 1994). From all this, we derive a protostellar envelope mass \(< 0.45 M_\odot\).

4. Modeling the SiO PV diagrams

We have used the 1D MHD shock code MHD_VODE (Flower & Pineau de Forêts 2015) to reproduce the SiO velocity structure measured along the north and south PV diagrams in G034 and to constrain the physical parameters of the shock. We have run a grid of models with shock speeds between \(v_s = 5-30\) km s\(^{-1}\), in accordance with the expanding and shocked velocities of the molecular gas in W44 (Sashida et al. 2013; Anderl et al. 2015b). We assume H pre-shock volume densities of \(n(H) = 10^4-10^5\) cm\(^{-3}\) (see Section 3.2) and consider cosmic-ray ionization rates \(\zeta = 1 \times 10^{-17} - 5 \times 10^{-15}\) s\(^{-1}\) (Vauquipe 2015), magnetic field strengths \(B_{mag} = 100-1000\) \(\mu\)G (Hoffman et al. 2005; Cardillo et al. 2014), and a pre-shock gas temperature of 15 K (Pillai et al. 2007; Ragan et al. 2011). The vLSR of the pre-shock gas ranges from 45 to 50 km s\(^{-1}\), in agreement with the velocities measured outside W44 (Section 3.1 and Sashida et al. 2013).

As shown in Figure 4, the SiO PV diagrams are best reproduced by time-dependent CJ-type shocks that have not reached steady state yet and that are still evolving. The velocity profiles of the neutral and ion fluids (\(v_n\) and \(v_i\)) are shown by solid and dashed magenta lines, respectively, while the drift velocity, \(v_d\), is shown by solid yellow lines. PV north can be fitted by a model with \(n(H) = 10^4\) cm\(^{-3}\), \(v_s = 22.5\) km s\(^{-1}\), \(\zeta = 5 \times 10^{-16}\) s\(^{-1}\), \(B_{mag} = 850\) \(\mu\)G, and \(\delta_{dyn} = 16,000\) yr. The SiO emission appears at distances where the drift velocity \(|v_n - v_d| > 0\), consistent with the idea that SiO is released by dust erosion/erosion in the shock. However, the SiO column density measured in G034 (1.6 \(\times 10^{12}\) cm\(^{-2}\); Section 3.2) cannot be predicted by the models. This may be due to the fact that the public version of the MHD_VODE code does not include grain–grain collision processes such as shattering. While the threshold drift velocities for the production of SiO by sputtering are \(>20\) km s\(^{-1}\) (Gusdorf et al. 2008; Jimenez-Serra et al. 2008), sputtering only requires velocities as low as 1 km s\(^{-1}\) (Guillet et al. 2011). The MHD_VODE code does not consider a small fraction of SiO in the dust mantles either, which may also alleviate the
discrepancy between the observed and predicted SiO column densities (see, e.g., Schilke et al. 1997; Jimenez-Serra et al. 2008).

As expected from the interaction with an SNR (Hoffman et al. 2005; Cardillo et al. 2014), the inferred value of $B_{\text{mag}}$ in PV north is higher than those measured in molecular clouds with $n(\text{H}_2) \sim 10^2$–$10^5 \text{ cm}^{-3}$ (Critcher et al. 2010). In fact, only models with such large $B_{\text{mag}}$ values can predict long dissipation lengths as observed in PV north.

In contrast to PV north, no model can reproduce well the sharp decrease in velocity observed in PV south. The best-fit model gives $n(\text{H}) = 10^4 \text{ cm}^{-3}$, $v_s = 23 \text{ km s}^{-1}$, $\zeta = 1 \times 10^{-15} \text{ s}^{-1}$, $B_{\text{mag}} = 880 \mu\text{G}$, and $17,000 \text{ yr}$. This mismatch between the model and the observations could be due to SiO (a high-density tracer) not being excited enough along the whole length of the shock. Alternatively, MHD shock theory may need to be revisited.

5. Discussion

5.1. SiO Emission Caused by Protostars and Outflows?

Our ALMA 3 mm continuum map does not reveal the presence of any pointlike source in G034 associated with the SiO emission down to a protostellar envelope mass $0.45 M_\odot$ (Section 3.3). This value is comparable to the lower limits of Class 0 and I envelope masses ($>0.5 M_\odot$; Arce & Sargent 2006) and well below the typical values for high-mass protostars ($>100 M_\odot$; Zhang et al. 2005). Therefore, if present, both low-mass and high-mass protostars should have been detected in our 3 mm ALMA image.

In addition, following Dierickx et al. (2015), we have estimated the mass ($M$), linear momentum ($P$), and kinetic energy ($E$) of the SiO emission in G034 to be $M = 12.2 M_\odot$, $P = 18.8 M_\odot \text{ km s}^{-1}$, and $E = 3.8 \times 10^{41} \text{ erg}$. Outflows driven by low-mass protostars have typical parameters in the ranges $M \sim 0.005$–$0.15 M_\odot$, $P \sim 0.004$–$0.12 M_\odot \text{ km s}^{-1}$, and $E \sim 2 \times 10^{40}$–$5 \times 10^{42} \text{ erg}$ (Arce & Sargent 2006). Although the kinetic energy inferred from SiO is comparable to that in outflows driven by low-mass protostars, the mass and linear momentum are factors 100–3000 higher. Outflows driven by high-mass protostars have masses of a few tens of $M_\odot$ and linear momentum $\sim 10$–$100 M_\odot \text{ km s}^{-1}$, comparable to our values (Zhang et al. 2005), but their kinetic energies are 5 orders of magnitude higher than measured in G034 (10$^{46}$ erg versus $3.8 \times 10^{41}$ erg; Zhang et al. 2005). It is thus unlikely that SiO in G034 is associated with star formation activity.

5.2. A Molecular Flow–Flow Collision Unveiled by Plunging Waves

G034 presents little star formation activity (Rathborne et al. 2006; Chambers et al. 2009), and hence internal stellar feedback is not expected to affect the pristine physical and chemical conditions of the cloud. In such a quiescent region, molecular shock tracers such as SiO are heavily depleted onto dust grains (Martín-Pintado et al. 1992; Schilke et al. 1997). Cosentino et al. (2018), however, reported the presence of widespread and narrow SiO emission (average line width of 1.6 km s$^{-1}$) toward the northwest of G034 at an angular resolution $\sim 30''$.
Our ALMA images reveal that SiO in G034 is organized into two plane-parallel structures that seem to impact onto the northwestern dense ridge of G034. In a way analog to a sea wave plunging onto a shore, the molecular gas pushed away by the W44 SNR (the sea wave) encounters the denser material of the IRDC (the beach), plunges, and breaks causing the formation of two plane-parallel wavefronts or MHD shocks seen in SiO. As shown in Section 4, such a kinematic structure is best reproduced by a nonstationary CJ-type MHD shock, where the J-type discontinuity is seen in the PV diagrams as an almost vertical velocity drop, and the C-type part shows a shallower deceleration over $\sim 10''$. The different velocity shapes of the SiO north and south PV diagrams may reflect inhomogeneities in the gas and/or slightly different physical conditions of the pre-shock gas (the derived $\zeta$ differ by a factor of 2 between PV north and south). The proximity of W44 is responsible for the high $\zeta$ and $B_{\text{mag}}$ required by the models.

The dynamical ages predicted for the shocks in PV north and PV south ($t_{\text{dyn}} = 16,000-17,000$ yr) are in agreement with the age of the SNR ($\sim 20,000$ yr) and the SiO depletion timescales ($\sim 10^4-10^5$ yr; Martín-Pintado et al. 1992). We also caution that the MHD_VODE code only provides 1D highly idealized models that do not consider projection effects, which may explain any disagreement between the model predictions and the observations (especially for PV south).

Finally, we propose that the shock interaction in G034 between the expanding molecular gas from W44 and the preexisting IRDC may have shaped the $A_v \geq 20$ mag ridge into its filamentary morphology, since the latter appears as an almost detached structure from the IRDC and since the SiO emission follows the shape of the ridge. This is supported by the fact that the density of the post-shock component in G034 is a factor $> 10$ higher than in the pre-shock gas ($n(H_2) > 10^5 \text{ cm}^{-3}$; Section 3.2), which may enable star formation. The lack of any cold core in the ridge is consistent with the idea that we are observing the earliest stages of such a process, since the age of the shock ($< 20,000$ yr) is too short to see the effects of gravitational collapse of any newly formed high-density structure or core (timescales $\sim 10^5$ yr for densities of $n(H_2) > 10^5 \text{ cm}^{-3}$; McKee & Tan 2003).

In summary, we report the first detection of a fully resolved, time-dependent CJ-type MHD shock. This shock has been produced by the interaction between a molecular flow expanding from the SNR W44 and a high-density ridge part.

---

Figure 4. SiO (color scale) north (top left) and south (top right) PV diagrams and corresponding $A_v$ profiles (bottom panels) extracted across the two SiO elongations. Velocity profiles predicted by the MHD_VODE code for the neutral (solid magenta line) and charged (dashed magenta line) fluids are shown along with the drift velocity ($v_{\text{drift}}$) between the two fluids (yellow line). Vertical dashed lines (in black) show the local peaks in extinction.

**Figure 5.** Spectra of C^{18}O(1–0) (black lines), C^{18}O(2–1) (blue lines), and SiO (2–1) (red lines) extracted toward G034 at positions α(J2000) = 18°56′43″, δ(J2000) = 1°23′28″ (top panel) and α(J2000) = 18°56′45″, δ(J2000) = 1°24′30″ over a 25″ beam. The components at 43″ and 40 km s^{-1} correspond to pre-shock and post-shock gas, respectively (vertical dashed lines).
