How Many Passengers Can We Serve with Ride-sharing?

Zeren Tan

August 2018

Abstract

Ride-sharing can reduce traffic congestion and thus reduce gas emissions and save travel time. However, transportation system with ride-sharing is currently inefficient due to low occupancy rate, high travel demand and some other factors. Existing literature did not consider ride-sharing with multi-request grouped in one trip. In our paper, we firstly proposed a graph-based algorithm that can obtain an approximation solution in polynomial time and then proposed an exact algorithm to solve this problem with maximizing the number of passengers served in $O(1.2312^{|E|})$ time.

Keywords: Ridesharing; Dynamic Matching; NP-Hard; Exact Algorithm

1 Introduction

Traffic congestion, air pollution and many other societal and environmental concerns are rising with the rapidly increasing number of vehicles on the road. The cost of congestion in the United States are 1% of its GDP, 5.5 billion hours of time lost to waiting in traffic congestion and 2.9 billion gallon of fuel wasted (Agatz et al., 2012; Alonso-Mora et al., 2017). The greenhouse gas and toxic gas emissions and their negative consequences have not even been taken into account. Traffic congestion is caused in many ways, among which low car occupancy rate is a fatal one. According to European Environment Agency, the average number of passengers in a single vehicle ranges from 1.0 to 1.8. Similar result has also been found in the United States(Santos et al., 2011; Agatz et al., 2012). Together with the high transportation demands, low vehicle occupancy rate leads to longer waiting time of a trip and sometimes longer distance travelled and finally costs the inefficiency of traffic system.

The huge costs brought by these negative effects of traffic congestion stimulate researchers, traffic operation agency as well as some companies to seek for a better solution. Big companies like Uber, Lyft and Didi have led a new transportation mode the so-called Mobility-on-demand (MoD) system, which improves the access to urban mobility with less waiting time and stress. MoD system is a more flexible and public transportation system that allows travelers to have more diverse demands. It is a user-centric approach which leverages emerging mobility services, integrated transit networks and operations, real-time data, connected travelers, cooperative Intelligent Transportation System (ITS) and incorporate shared-use and multimodal integration.

In ride-sharing, travelers with similar itineraries (i.e. similar departure time, similar arrival time, similar origin and destination) are grouped together. With ride-sharing, the driver involved in a trip can get more revenues without driving longer distance and passengers sharing a ride should pay less for this ride as they share their ride with others. The travel expenses are reallocated among ride-share participants but different passengers should benefit differently. Some participant may travel longer distance in order to pick up other participants and sometimes cannot reach his/her destination on time while other participants just share a ride with others without travel more. The way to determine how to reallocate the trips costs is an important problem that some researchers are working on.

Existing studies mainly focus on ride-sahring without pooling requests(Pavone et al., 2012; Spieser et al., 2014; Zhang and Pavone, 2016; Spieser et al., 2016). But they did not consider servicing several travel request into a single trip. The best result we know is (Alonso-Mora et al., 2017). They proposed a near-optimal solution that is tractable in practical application.

2 Problem Statement

2.1 Assumptions

There are several major assumptions related to the following discussion:
1. The time interval considered is sufficiently small so that there will not be any extra taxis arriving except the taxis we have observed at the beginning.

2. For each passenger, if the gain he get for sharing a ride is greater than the loss, which is acceptable, he is willing to take the ride.

3. A taxi driver is willing to give a ride as long as the distance is within his acceptable distance and he can get the mean value of the income he used to get regarding of similar time interval and similar travel distance.

Table 1: Notations

| Notation | Description |
|----------|-------------|
| \( \mathcal{P} \) | The set of passengers |
| \( N_i \) | The set of passengers who are close (see Definition 2.1) to passenger \( i \) |
| \( \mathcal{O} \) | The set of origins |
| \( \mathcal{D} \) | The set of destinations |
| \( \mathcal{DT} \) | The set of expected departure time |
| \( \mathcal{AT} \) | The set of latest arrival time |
| \( G_i \) | The group of passengers, which contains \( i \), who are all close to each other |
| \( M_i \) | The set of possible group rides for passenger \( i \) |
| \( \text{Loss}_{im} \) | The loss of passenger \( i \) to join the group ride \( m \) |
| \( \mathcal{O}_m \) | The final departure location for group ride \( m \) |
| \( \mathcal{D}_m \) | The final destination for group ride \( m \) |
| \( \mathcal{DT}_m \) | The final departure time for group ride \( m \) |
| \( \mathcal{AT}_m \) | The final arrival time for group ride \( m \) |
| \( \mathcal{M} \) | The set of all possible trips |
| \( \text{Dis}_{im} \) | The discount passenger \( i \) gain in ride \( m \) |
| \( \text{Pay}_{im} \) | The amount of money passenger \( i \) pays the driver in group ride \( m \) |
| \( f_i \) | The amount of money passenger \( i \) should pay the driver without sharing a ride |
| \( \delta \) | The constant threshold for distance in the definition of close |
| \( t \) | The constant threshold for time in the definition of close |
| \( \Delta_m \) | The average income for driver matched with group ride \( m \) that he could get without ride-sharing |
| \( r_m \) | Passengers who take the ride \( m \) |
| \( c_i^m \) | An indicator variable, 1 if passenger \( i \) take the group ride \( m \); 0 otherwise |
| \( \zeta \) | The acceptable loss for each passenger when sharing a ride |
| \( \mathcal{B} \) | The set of available taxis |
| \( \bar{v} \) | The average driving velocity |
| \( z_b^m \) | An indicator variable, 1 if taxi \( b \) is matched with group ride \( m \); 0 otherwise |
| \( d_b^m \) | The distance taxi \( b \) should travel in order to start trip \( m \) |
| \( \xi \) | The acceptable distance drivers are willing to travel in order to start a trip |

Definition 2.1 (Close). For passengers \( i, j \in \mathcal{P} \), they are close to each other if and only if \( ||\mathcal{O}_i - \mathcal{O}_j||_{M} \leq \delta \), \( ||\mathcal{D}_i - \mathcal{D}_j||_{M} \leq \delta \) and \( |\mathcal{DT}_i - \mathcal{DT}_j| \leq t \), where \( ||\cdot||_{M} \) stands for the Manhattan distance.

We introduce this definition to ensure each passenger in a reasonable group of two or more passengers does not need to walk a lot and wait for too long in order to start a trip or reach his destination. If it is satisfied, we can simply ask them to meet at the geometric center of their requested origins and depart for the geometric center of their expected destinations. If it is not satisfied, a passenger may not want to share a ride with others and may violate.

\[
\max \sum_{b \in \mathcal{B}} \sum_{m \in \mathcal{M}} |r_m| z_b^m
\]
\[
s.t. \sum_{m \in M_i} c_i^m \leq 1 \quad \forall i \in \mathcal{P} \tag{1}
\]
\[
c_i^m = c_j^m \quad \forall i, j \in r_m \quad \forall m \in \mathcal{M} \tag{2}
\]
\[
\sum_{b \in \mathcal{B}} z_b^m \leq 1 \quad \forall m \in \mathcal{M} \tag{3}
\]
\[
\sum_{m \in \mathcal{M}} z_b^m \leq 1 \quad \forall b \in \mathcal{B} \tag{4}
\]
\[
d_b^m \leq \xi \tag{5}
\]
\[
\text{Loss}_i^m \leq \text{Gain}_i^m \quad \forall i \in \mathcal{P}, m \in \mathcal{M} \tag{6}
\]
\[
\Delta_m \leq \sum_{i \in r_m} \text{Pay}_i^m \quad \forall m \in \mathcal{M} \tag{7}
\]
\[
\text{Loss}_i^m \leq \zeta \quad \forall i \in \mathcal{P}, m \in \mathcal{M} \tag{8}
\]
\[
c_i^m, z_b^m \in \{0, 1\} \quad \forall i \in \mathcal{P}, b \in \mathcal{B}, m \in \mathcal{M} \tag{9}
\]

where \(\text{Loss}_i^m, \text{Gain}_m^m, \text{Dis}_i^m, f_i, \Delta_m\) are defined as follows:

\[
\text{Loss}_i^m = \text{Function}(||O_i - O_j^m||_M + ||D_i - D_j^m||_M, ||D T_i - D T_j^m||)
\]
\[
\text{Gain}_i^m = \text{Dis}_i^m \cdot f_i
\]
\[
\text{Dis}_i^m = \text{Function}(||O_i - O_j^m||_M + ||D_i - D_j^m||_M, ||D T_i - D T_j^m||, ||O_i - D_i^m||_M)
\]
\[
f_i = \text{Function}(||O_i - D_i^m||_M)
\]
\[
\Delta_m = \text{Function}(||O_i - D_i^m||_M, ||D T_j^m - A T_j^m||)
\]

The objective function is to maximize the total number passengers served by taxis. Constraint 1 suggests that each passenger can take at most one taxi and it is possible that some passengers may not have taxi to take. Constraint 2 ensures the validity of group ride \(m\). Constraint 3 and Constraint 4 state that each taxi can be matched with at most one ride and each ride can be matched with at most one taxi. Constraint 5 and Constraint 7 guarantee that the solution is feasible for taxi drivers. Constraint 6 and Constraint 8 make sure that the rides grouped are feasible for passengers. Constraint 9 illustrates that the optimization problem is a 0-1 integer programming problem (IPP).

### 3 A Graph-Based Algorithm

#### 3.1 Group Ride and Initial Graph

In order to group passengers, we introduce the definition of stable pair.

**Definition 3.1** (Stable Pair). Two passengers \(i, j \in \mathcal{P}\) are a stable pair if and only if they are close to each other and \(\text{Gain}_i^m \geq \text{Loss}_i^m, \text{Gain}_j^m \geq \text{Loss}_j^m \quad \forall m \in M_i \cap M_j\).

**Definition 3.2** (Stable Group). A group of passengers is a stable group if and only if each two of them form a stable pair.

From the definition of stable group, it can be concluded that passengers can form a stable group ride are indifferent to their partners. We further assume that passengers in different stable groups cannot form any stable group. That is, we can divide passengers into several groups based on with regard to stable groups. Passengers in different stable group can never share a ride.

While this condition is somewhat restrictive, there are some practical applications that meet this condition. For instance, in the international airport, passenger in Terminal 1 may not want to go to Terminal 2 or other terminals to take a taxi. Passenger in the same terminal can form a stable group while passengers in different terminal cannot. Passengers are naturally divided into several stable groups in this example.

#### 3.2 Graph Construction Algorithm

We input the stable groups of passengers and the set of taxis. In each group, passengers are all willing to share the same ride with other people. An example of the initial graph is presented in Figure 1.
Algorithm 1: ConstructGraph\((P, B)\)

1. Initialize \(E \leftarrow \emptyset\);
2. for \(p \in P\) do
   3. \(E \leftarrow E \cup \{(p, t)\}\);
4. for \(b \in B\) do
   5. if \(b\) is willing to give a ride to \(p\) then
   6. \(E \leftarrow E \cup \{(s, b), (b, p)\}\);
7. end
8. end
9. end
10. return \(E\)

3.3 Algorithm Design

In order to solve this problem, we choose to abstract this problem as a graph by the following steps.

Step 1 We abstract set of taxis and set of passengers as “small nodes”.

Step 2 A stable group of passengers is abstracted as a “super node”.

Step 3 There is an edge between the “super node” contains passengers and the taxi node if and only if the driver is willing to give the passengers a ride.

Step 4 We construct a graph \(G = (V, E)\) with these nodes and add a source node and a sink node. The source node has edges with taxi nodes and the sink has edges with nodes contain passengers.

Step 5 Each edge \(e \in E\) has a capacity \(c_e\) which is defined as follows:

\[
c_e = \begin{cases} 
\lceil \frac{\text{number of passengers in } v}{4} \rceil & e = (v, t) \\
1 & \text{otherwise}
\end{cases}
\]

Figure 2 and Figure 3 illustrate the abstraction process.

Everyone in the same passenger super node is indifferent to who are going to take the same taxi with him/her as long as they are in the same node. Thus, we are not concerned about the allocation of passengers to taxis. The main problem we are going to discuss is how to develop an algorithm that can determine the most effective distribution of taxis so that the system can serve the most passengers. That is, the algorithm we are going to develop can return how many taxis will be sent to each passenger super node. When taxis arrive, we can use constant time for each taxi to decide the way of assigning passengers. Because the amount of taxis arrive for each passenger super node \(p\) is less than or equal to \(\lceil \frac{|P|}{4} \rceil\) and the total number of taxis arrive is not greater than \(|B|\), the running time of assigning passengers is \(O(|P| + |B|)\).

Definition 3.3 (Maximum-Flow). A flow network is a directed graph \(G = (V, E)\) with a source node \(s \in V\), a sink \(t \in V\) and capacities along each edge. The amount of flow between two vertices is described by a mapping \(f : V \times V \to \mathbb{R}\). The flow of a graph has the following properties:

\[
f_e \leq c_e \quad (10)
\]

\[
f(u, v) = -f(v, u) \quad \forall u, v \in V \quad (11)
\]

\[
\sum_{w \in V} f(v, w) = 0 \quad \forall v \in V - \{s, t\} \quad (12)
\]

The total flow \(|f|\) of a flow network is the amount of flow going out the source (or equivalently going to sink). Specifically, \(|f| = \sum_{v \in V} f(s, v)\). The maximum-flow of a flow network is the largest possible flow for a given graph \(G\).

We can show that the constraints stated above are all satisfied by the maximum-flow problem illustrated in Figure 3.

1. In the same passenger super node, origins and destinations of all passengers are close and when they are grouped together, their gain is greater than their loss. Thus, Constraint 6 and Constraint 8 are satisfied.
4. Theorem 3.4 illustrate that there exist a integral maximum-flow since all capacities are defined as integers. Hence, while loop will definitely stop in other augmenting paths. This strategy ensure that the aforementioned bad situation would not exist. The rigorous value of the score is defined as following: when there is a taxi is to say, the solution serves the most passengers and thus is optimal.

If Proposition 3.5. write as a proposition.

Algorithm 3 will terminate in finite steps.

Because we only augment flow value by 1 per time and one upper bound for the maximum flow is $|B|$, the first while loop will definitely stop in $O(|B|)$ times. Since each time when the second while loop runs, the score for taxi $b$ will increase by 1, for each taxi, the while loop will only run 4 times. Therefore, the second while loop will run $O(|B|)$ times.

Assertion 3.8. The solution found by Algorithm ?? and Algorithm ?? is optimal.

Proof. The meaning of the score a taxi $b$ get is the number of passengers it takes and thus the total score $g$ represents the total number of passengers the assignment of taxis can serve. From Algorithm 2 and the augmenting step of Algorithm 3, we can observe that $g$ and the score of a taxi $b$ are both non-decreasing with respect to the augmenting step. In addition, note that each node $p \in P$ if ever matched, it would be always matched even though the set of taxis match with $p$ might change.

Assertion 3.9. After each augmenting step, the total score $g$ the flow obtain is non-decreasing.
Algorithm 2: OneAugment\((f, g, c, r)\)

1. for edge \(e \in r\) do
2.   \(u \leftarrow\) tail of \(e\);
3.   \(v \leftarrow\) head of \(e\);
4.   if \(e \in E\) then
5.     if \(v \in P\) then
6.       \(g_v^c \leftarrow (g_v \mod 4)\);
7.       \(g \leftarrow g + g_v^c\);
8.       \(g_v \leftarrow g_v - g_v^c\);
9.     end
10.    \(f(e) \leftarrow f(e) + 1\);
11.   else
12.     if \(u \in P\) then
13.       \(g \leftarrow g - g_u\);
14.     end
15.    \(f(e^R) \leftarrow f(e^R) - 1\);
16. end
17. return \(f\) and \(g\)

Algorithm 3: Modified-Ford-Fulkerson\((G, s, t, c)\)

1. for edge \(e \in E\) do
2.   \(f(e) \leftarrow 0\);
3. end
4. while there exists some augmenting path \(r\) in \(G_f\) do
5.   \(f, g \leftarrow OneAugment(f, g, c, r)\);
6.   Update \(G_f\);
7. end
8. while there exist a passenger node \(p_1\) for \(b \in B\) from which \(b\) can get more scores do
9.   \(p_0 \leftarrow\) the node \(b\) is now sent to;
10.  \(g \leftarrow g + g_{p_1}^{(b, p_1)} - g_{p_0}^{(b, p_0)}\);
11.  Update \(G_f\);
12 end
13 return \(f\)
Proof. We assume that the score before augmenting is $g_0$. From Algorithm 2, along an augmenting path $r$, we have three cases to discuss:

Case 1 If there exist an edge $e_1 \notin E, e_1^R \in E$, then there must exist $p_1 \in P$ which is the tail of $e_1$ and $b_1 \in B$ which is the head of $e_1$. When augmenting, we assume that $e_2 = (b_2, p_1)$ is an edge of the augmenting path. Then, $g_{p_1}^{e_2} = g_{e_1}^{R}$. Assuming $e_3 = (b_1, p_2)$ is an edge of the augmenting path. We further assume that $p_2$ was not assigned any taxi before augmenting. There must exist this kind of node, otherwise, there will not have any augmenting path. Therefore, the total score $g = g_0 + g_{p_2}^{R} > g_0$.

Case 2 If there does not exist $e \notin E, e_R \in E$ in augmenting path, then it is obvious that the flow value increase 1 and the score increase as well.

Case 3 If there is no augmenting path regarding of flow, then in the last for loop of Algorithm 3, we can easily find that $g$ is non-decreasing.

To summarize, total score $g$ is non-decreasing.

Assuming that the solution found by Algorithm ?? and Algorithm ?? is not optimal. Then, from Assertion 3.6 and Proposition 3.5, we can conclude that the aforementioned situation must exist. That is, there exist one taxi $b_0$ that has edges with two passenger super nodes and $b_0$ is assigned to one node $node_1$ that $|q|$ passengers in $node_1$ take $b_0$ but in another node $node_2$ there is $|Q| > |q|$ passengers waiting for a taxi.

If we think about why $b_0$ finally choose to take $q$, it turns out that when $b_0$ takes $q$, it can get more scores as how Algorithm 3 is implemented. The scores it has represent the number of passengers it takes. Therefore, $|Q| \leq |q|$. This is a contradiction.
4 Running Time

4.1 Running Time of Algorithm 1

In this section, we analyze the total running time of our algorithm. In Algorithm 1, all the steps take $O(1)$. Therefore, the total running time is $O(|B||P|)$.

4.2 Running Time of Algorithm 2

It is easy to observe that each path in $G_f$ has only $O(|B|)$ edges. The step looking up if $v$ is in $P$ takes $O(1)$ on average. So the average running time for Algorithm 2 is $O(|B|)$.

4.3 Running Time of Algorithm 3

The running time for the initialization step is $O(|P|)$. Since $O(|B|)$ for OneAugment($f, g, c, r$), the steps in the first while loop take $O(|B|)$. And this is the most expensive step in the first while loop. To compute the running time for the first while loop, we need to figure out the times this first while loop will run. Since we only augment 1 flow value per time, the first while loop will run at most $|B|$ times. Therefore, the total running time is $O(|B|^2)$.

The second while loop will run for at most $|B|$ taxis and as stated in Proof 13, it will run at most 4 times for each taxi and $O(|P|)$ per time. Thus, the total running time for the second while loop is $O(|B||P|)$.

4.4 Total Running Time of Algorithms

By summarizing the running time analysis of the above three subsections, we can conclude that the total running time is $O(|B||P| + |B|^2)$.

5 Proof of NP-Hard

We reduce our problem into a NP-Complete problem–Complete Coloring. In the language of graph theory, the decision problem of complete coloring can be phrased as following:

Given a graph $G = (V,E)$ and an integer $k$, find the answer that if there exist a partition of $V$ into $k$ or more disjoint subsets $V_1, V_2, \ldots, V_k$ such that each $V_i$ is an independent set of $G$ and for each pair of $V_i, V_j, V_i \cup V_j$ is not an independent set of $G$.

Proof. Given an instance of Complete Coloring problem, we can create an instance of our problem by the following method.

Denote $P$ as the set of passengers and a passenger $p_i$ as a node. For each pair of passengers who cannot form a stable pair, we attach an edge $e$ with them. Assuming that for all vehicles $b \in B$, it can take either of these passengers and the capacity of vehicle is large enough.

The mapping can be constructed as following: let each vertex $v_i$ in $G$ be vertex $p_i \in P$ and let independent set $V_i$ be vehicle $b_i \in B$. It can be observed that passengers that can form a stable trip can be collected as an independent
set. So the nodes have the same color form a stable trip and are assigned into a vehicle. The set of passengers a vehicle contains is an independent set of the graph. It is obvious that if there is a solution for our problem, that is, if there exist an assignment of vehicles and passengers, the Complete coloring problem can be solved. If there is a partition of $G$ satisfies the aforementioned property, there is a assignment of vehicles and passengers.

6 A Branch and Bound Based Algorithm

6.1 Graph Construction Algorithm

Algorithm 4

---

Algorithm 4: VTG($G$)

1. $\mathcal{T} \leftarrow \emptyset$; $\mathcal{E} \leftarrow \emptyset$;
2. for $i$ from 1 to $\nu$ do
3.     $\mathcal{T}_i \leftarrow \emptyset$
4. end
5. for $e = (b, v) \in G$ do
6.     $\mathcal{T}_1 \leftarrow \mathcal{T}_1 \cup \{v\}$;
7.     $\mathcal{E} \leftarrow \mathcal{E} \cup \{(b, v)\}$;
8. end
9. for $\forall v_1, v_2 \in \mathcal{T}_1$ and $e = (v_1, v_2) \in G$ do
10.    $\mathcal{T} \leftarrow \{v_1, v_2\}$;
11.    $\mathcal{T}_2 \leftarrow \mathcal{T}_2 \cup \mathcal{T}$;
12.    $\mathcal{E} \leftarrow \mathcal{E} \cup \{(v_1, T), (v_2, T)\}$;
13. if $(b, v_1), (b, v_2) \in G$ then
14.     $\mathcal{E} \leftarrow \mathcal{E} \cup \{(b, T)\}$;
15. end
16. end
17. for $j$ from 3 to $\nu$ do
18.     for $\forall T_1, T_2 \in \mathcal{T}_{j-1}$ and $|T_1 \cup T_2| = j$ do
19.         Denote $T_1 \cup T_2 = \{v_1, v_2, \ldots, v_j\}$;
20.         if $\forall k \in \{1, 2, \ldots, j\}, \{v_1, v_2, \ldots, v_j\}\setminus v_k \in \mathcal{T}_{j-1}$ then
21.             $\mathcal{T} \leftarrow \mathcal{T}_1 \cup \mathcal{T}_2$;
22.             for $i$ from 1 to $j$ do
23.                 $\mathcal{E} \leftarrow \mathcal{E} \cup \{(v_i, T)\}$;
24.             end
25.             if $b$ can take trip $T$ then
26.                 $\mathcal{T}_j \leftarrow \mathcal{T}_j \cup T$;
27.                 $\mathcal{E} \leftarrow \mathcal{E} \cup \{(b, T)\}$;
28.             end
29.         end
30.     end
31.     $\mathcal{T} \leftarrow (\bigcup_{i \in \{1, \ldots, \nu\}} \mathcal{T}_i) \cup \mathcal{T}$;
32. end
33. for each vehicle $b \in \mathcal{B}$ do
34.     for $t \in \mathcal{T}$ do
35.         if $b$ is able to take trip $t$ then
36.             $\mathcal{E} \leftarrow \mathcal{E} \cup \{(b, t)\}$
37.         end
38.     end
39. end
6.2 Proof of Correctness

Assertion 6.1. The algorithm can return the optimal solution for the original ILP.

Proof. Constraints
1. When a vehicle is selected in the process, that is for one of its outgoing arc \( e_i \in E, s_i = 1 \), it will not be selected in the upcoming process since all of its outgoing edges will be deleted once it is selected. This indicates that each vehicle is only matched with one trip.
2. As long as for an edge \( e_i, s_i = 1 \), the incoming arcs of the matched trip and its neighbors will be removed from graph \( G \). So a trip will be only matched with one vehicle.
3. When deleting all the incoming arcs of a trip, the scanning process is going to detect which trip is incompatible with the selected trip and those trip will be remove from \( G \) in the end of the scanning process. Hence, all passengers will be assigned to exactly one trip in the final solution.

Optimality We prove this by contradiction.
Suppose that there is an optimal solution of the ILP that can not be returned by the algorithm. Assuming that the selected edges of the optimal solution are \( e_n, e_{n+1}, \ldots, e_{n_k}, \) this is \( s_i = 1 \) \( \forall i \in \{1, \ldots, k\} \) should be returned by a correct algorithm. Then go back to see what the algorithm does. In the first step, \( s_1 = 0 \) or 1 is determined by the algorithm. If \( s_1 \) is assigned as 0, only one arc will be deleted and the algorithm will see what \( s_2 \) should equal to. If \( s_2 = 0 \), then the algorithm will go on to see which value should be assigned to \( s_3 \). The process goes on. When the algorithm reach the point of deciding the value of \( s_n \), either 0 or 1 is the possible choice. The algorithm will explore the two choices in the whole process. When \( s_n = 1 \) is going to be explored, the algorithm will go on to determine the value of \( s_{n+1}, \ldots, s_{n_k} \). The assignment that \( s_k = 0 \) \( \forall k \in \{n+1, \ldots, n_k-1\} \) is included in the search space of the algorithm. As long as the algorithm set all of \( s_{n+1}, \ldots, s_{n_k} \) to be 0 when exploring, this assignment will be returned. And then the algorithm will determine the value of \( s_{n_k} \). When it is going to exploring the solutions when \( s_{n_k} = 1 \), the process goes on. Until the algorithm is going to find what will happen if \( s_{n_k} = 1 \), the process ends since all the arcs are removed and this branch is done.

From the above statement, it can be observed that the assignment \( s_{n_1}, s_{n_2}, s_{n_3}, \ldots, s_{n_k} \) = 1 is included in the search space of the algorithm. Hence, if the solution is optimal, it will certainly be returned by the algorithm.

6.3 An Example for Algorithm Implementation
Consider the Vehicle-Trip graph in Figure 4, the steps for Algorithm 5 is shown in Figure 5.

Step 1 Enumerate all edges as 1, 2, \ldots, 12 from top to down.

Step 2 When \( s_1 = 1 \), vehicle \( b_1 \) is matched with trip one that contains passenger number one. Then arcs associated with \( b_1 \), node 1, node 1, 2, node 1, 3 and node 1, 2, 3.
Algorithm 5: BranchBound($G$)

1  Find the set of connected components $C$;
2  if $|C| > 1$ then
3      $W \leftarrow \emptyset$;
4      $S \leftarrow \emptyset$;
5      for $c \in C$ do
6          $w_c, s_c \leftarrow \text{BranchBound}(G_c)$;
7          $W \leftarrow W + w_c$;
8          $S \leftarrow S \cup s_c$;
9      end
10  else
11      Enumerate all edges in $E$ from 1 to $n = |E|$ if needed;
12      $e_1 = (u_1, v_1) \leftarrow$ the first edge of $E$;
13      $G_1 \leftarrow G$ removing $e_1$;
14      $G_2 \leftarrow G$ removing $e_1, u_1, v_1$, all outgoing arcs of $u_1$ and all incoming arcs of $v$ and its neighbors;
15      for $v \in V_2$ do
16          if $u \cap u_1 \neq \emptyset$ then
17              Remove $u$ and its incoming edges from $G_2$;
18          end
19      end
20  end
21  $W_1, S_1 \leftarrow \text{BranchBound}(G_1)$;  $W_2, S_2 \leftarrow \text{BranchBound}(G_2)$;
22  if $W_1 > W_2$ then
23      return $W_1, \{s_1 = 0\} \cup S_1$;
24  else
25      return $W_2, \{s_1 = 1\} \cup S_2$;
26 end
Step 3 Then it comes to the point of $e_{10}$. If $s_{10} = 1$, then it is done.

Step 4 If $s_{10} = 0$, then the algorithm will see the assignment of $s_{11}$. If $s_{11} = 1$ is assigned, then it is done.

Step 5 If $s_{11} = 0$, then the value of $s_{12}$ will be determined. If $s_{12} = 1$, then this path is finished.

Step 6 If $s_{12} = 1$, in this example, the solution is not optimal at all. Actually, it should be categorized as infeasible solution since $b_2$ is not matched with any trip while it really could.

- The steps go on like the above process. The algorithm will terminate when all possibilities are explored. The solution(s) with maximum passengers is returned as the result. For the final result, the comparison among these passenger-optimal solutions will be made in terms of the weight and the one with maximum weight will be returned in the end. This can be done in polynomial time.

### 6.4 Running Time of Algorithm 5

From the algorithm, it can be implied that the running time of Algorithm 5 can be obtain by solving the following equation.

$$T(|\mathcal{E}'|) = T(|\mathcal{E}'| - 1) + T(|\mathcal{E}'| - d_b - \sum_{i=0}^d d_{v_i} + d + 1) + O(|\mathcal{B}'| - 1 + |\mathcal{V}'| - d - 1)$$

where $d_b$, $d_{v_i}$, $d$ represent the outgoing, incoming degree and the number of neighbors of selected node, respectively, and $\mathcal{E}'$, $\mathcal{V}'$, $\mathcal{B}'$ are the current edges, trip nodes, vehicles nodes, respectively.

Next, the method of solving this equation is presented as following.

Case 1 If $d = 0$, it means the trip only contains one passenger, then the problem can be reduced to a maximum weight bipartite matching problem. It can be solved in polynomial time by Hungarian method.

Case 2 If a vehicle only has edges with trips formed by a stable group, then we can simply match a vehicle with the node, which it connects with, contains the most passengers. This can be done in polynomial time too.

Case 3 If neither of the above cases exist, an approximation of $-d_b - \sum_{i=0}^d d_{v_i} + d + 1$ can be given. Since $d_b \geq 6$, $\sum_{i=0}^d d_{v_i} \geq 2(d + 1)$ and $d \geq 1$, then $d_b + \sum_{i=0}^d d_{v_i} - d - 1 \geq 8$. In worst case, $d_b + \sum_{i=0}^d d_{v_i} - d - 1 = 8$. 

![Figure 5: Example](image-url)
In this case, the original problem of solving Equation 13 except the last term becomes solving the polynomial equation

\[ x^8 = x^7 + 1 \]  

(14)

A real-value root of this equation is \( x = 1.2321 \). Since the last term of Equation 13 is added only when the current edge the algorithm explores is assigned as 1, and in the final solution, the number of edges assigned as 1 is no more than the number of vehicles. In addition, the incidental term decreased when \( s \) of one edge is assigned as 1. Therefore, the incidental running time of scanning is \( O(|B|^2) \). Hence, the running time of Algorithm 13 is \( O(1.2321^{|E|} + |B|^2) \) in terms of the worst case.

If the algorithm is expected to detect the infeasible solutions, then it needs more space to remember how many vehicles and stable groups left for each path. If the algorithm does not remove infeasible solutions and do not go on the detecting process, then it needs more space to remember the states of each edge.

7 Experiments

7.1 Data

The datasets from NYC TLC are used to evaluate the performance of the proposed algorithms. The datasets include the pickup and dropoff location and time of a recorded trip. We choose the data in a relatively small area of Manhattan and use trips detected in that place. To be specific, trips served in the rectangle area formed by ( ) and ( ). Trips during 8:15-8:30 a.m. are extracted to verify the feasibility of our algorithms.

8 Conclusion

In this paper, we introduced a reactive anytime optimal method with scalable real-time performance for assigning passenger requests to a fleet of vehicles of varying capacity. We quantify experimentally the tradeoff between fleet size, capacity, waiting time, travel delay, and operational costs for low- and medium-capacity vehicles, such as taxis or vans in a large-scale city dataset. Under the assumption of one person per ride, we show that 98% of the taxi rides currently served by over 13,000 taxis could be served with just 3,000 taxis of capacity four. We observe that a vehicle capacity of two is sufficient for ride-sharing when a small trip delay of 2 min is imposed. If a maximum delay of 5 min or more (comparable to the time spent retrieving a car from parking) is allowed, higher-capacity vehicles (i) increase the service rate significantly, (ii) reduce the waiting time, and (iii) reduce the distance traveled by each vehicle. Our analysis shows that a ride-pooling service can provide a substantial improvement in urban transportation systems and that the system parameters such as vehicle capacity and fleet size depend on quality of service requirements and demand.
