(Dated: September 8, 2009)

We put forward double perovskites of the R$_2$NiMnO$_6$ family (with $R$ a rare-earth atom) as a new class of multiferroics on the basis of ab initio density functional calculations. We show that changing $R$ from La to Y drives the ground-state from ferromagnetic to antiferromagnetic with $\parallel \downarrow \parallel \uparrow \downarrow \downarrow \uparrow \downarrow \downarrow$ spin patterns. This $E^*$-type ordering breaks inversion symmetry and generates a ferroelectric polarization of few $\mu$C/cm$^2$. By analyzing a model Hamiltonian we understand the microscopic origin of this transition and show that an external electric field can be used to tune the transition, thus allowing electrical control of the magnetization.

Materials with simultaneous magnetic and ferroelectric ordering – multiferroics – are attracting enormous scientific interest due to their potential for applications in memory and data storage devices [1, 2]. Multiferroics with magnetically induced ferroelectric order are particularly interesting due to their strong magneto-electric coupling, which is required for an electric (magnetic) control of magnetic (electric) order parameter: a very desirable property from a technological point of view [3]. Therefore, the search for new multiferroics with the ferroelectric order driven by the magnetic order is currently a very active and important field of research.

In this letter, we show, by using first-principles density functional theory (DFT) calculations and a model Hamiltonian analysis, that the magnetic order in the double perovskite compounds R$_2$NiMnO$_6$ (RNMO) changes from ferromagnetic for $R$=La and Sm to the $E^*$-type for $R$=Y. The $E^*$-type magnetic structure consists of $\parallel \downarrow \parallel \downarrow \downarrow \uparrow \downarrow \downarrow \downarrow$ spin chains along the cubic perovskite-like directions (see Fig. 3), or equivalently, zig-zag ferromagnetic (FM) spin-chains antiferromagnetically coupled in-plane to the neighboring zig-zag chain, with an out-of-plane FM coupling [4]. $E^*$-type magnetism breaks inversion symmetry and thus allows a ferroelectric polarization to occur. We will show that indeed Y$_2$NiMnO$_6$ is multiferroic with an electric polarization of few $\mu$C/cm$^2$. We will show that vice versa the magnetic transition from ferro to $E^*$-type can be tuned by an external electric field, thus allowing electric control of the ferromagnetic order parameter.

The double perovskite La$_2$NiMnO$_6$ (LNMO) is a ferromagnetic insulator with a Curie temperature close to room temperature ($T_c \approx$ 280 K). The structure of LNMO changes from rhombohedral ($R\bar{3}$) at high temperature, to monoclinic with $P2_1/n$ symmetry group at low temperature [5, 6]. DFT has been successful in understanding the ferromagnetic (FM) insulating behaviour and the dielectric anomalies observed experimentally in LNMO [7, 8]. We work in the framework of density-functional theory, using the Vienna ab initio simulation package [9], in which the Kohn-Sham equations are computed using the projector augmented wave method (PAW) and solved describing electronic exchange and correlation in the generalized gradient approximation (PBE) [10, 11].

The spin resolved density of states (DOS) of LNMO is shown in Fig. 1a) and they agree well with the one in Ref. [7]. The octahedral surrounding of Mn and Ni atoms split the Mn-d and Ni-d manifolds into the $t_{2g}$ and $e_g$ levels. In the spin up channel the Ni-$t_{2g}$ and Ni-$e_g$ are found within the range of 2 eV below the Fermi level ($E_F$) mixed with O-p and the Mn-$t_{2g}$ states, the latter being localized between the Ni-$t_{2g}$ and the Ni-$e_g$. The Mn-$e_g$ remain empty, separated by $\sim$2.5 eV from the

FIG. 1: (Color online) (a) Density of states in $P2_1/n$ symmetry for FM-type magnetic structure in LNMO; (b) Density of states in $P2_1$ symmetry for $E^*$-type magnetic structure in YNMO. Zero energy is set to be Fermi level.
Mn-t$_2$g. In the down spin channel the Ni-t$_2$g states are located between the O-p and the Fermi level, while the Ni-c$_g$ lie above the Fermi level along with the Mn-t$_2$g and the Mn-c$_g$. This distribution of states corresponds to the nominal valences Ni$^{2+}$ ($d^8$) and Mn$^{4+}$ ($d^3$): the magnetic moments in our simulations are indeed found to be 1.4 $\mu_B$ and 2.9 $\mu_B$, respectively, close to the experimental values \[2\].

Calculating the DFT total energies of the different magnetic structures on the relaxed crystal structure of LNMO and using a least square mean method to fit their values by an effective Heisenberg Hamiltonian (as in Ref. \[13\]), we extract the magnetic couplings $J_{ij}$ \[14\].

| R   | $J_{NN}$ | $J_{NN}$ | $J_{N}$ | $J_{NN}$ | Q |
|-----|----------|----------|---------|----------|---|
| La  | -100     | 3        | 44      | 47       | 2.13 |
| Sm  | -72      | 3        | 27      | 25       | 2.88 |
| Y   | -57      | 2        | 11      | 12       | 4.75 |

TABLE I: Values of the exchange interactions, $J_{ij}$ (in meV/$\mu_B^2$), for R$_2$NiMnO$_6$ (RNMO) with rare earths R=La,Sm,Y: $J_{NN}$($\parallel$Ni-Ni), $J_{NN}$($\parallel$Mn-Mn), $J_{N}$($\parallel$Ni-Mn) and $J_{NN}$($\perp$Ni-Mn) denote the in-plane Ni-Ni second-nearest neighbor, in-plane Mn-Mn second-nearest neighbor, out-of-plane Ni-Mn nearest-neighbor and in-plane Ni-Mn nearest-neighbor exchange constants, respectively. The ratio (Q) between $J_{NN}$($\parallel$Ni-Ni) and $J_{NN}$($\parallel$Ni-Mn) is reported in the last column.

Experimentally, the unit cell parameters of double perovskites R$_2$NiMnO$_6$ with R = Sm, Y are unknown. Since the theoretical lattice parameters of LNMO obtained within GGA are very close to the experimental estimates (see also Ref. \[2\]), we infer a good accuracy for the prediction of structural properties. Therefore, we determine the lattice parameters and the internal coordinates of the ions for R=Sm, Y by carrying out the first-principles volume and shape optimization for the monoclinic phases upon imposing a FM spin configuration. Our results may provide basis to refine the crystallographic structures experimentally \[15\]. A general trend is found: a smaller size of the radius of the rare earth is such to decrease the Ni-O-Mn angles increasing the octahedral distortions, which in turn reduces the effective interactions between Ni and Mn ions. Following this procedure, the total energies of different magnetic structures as considered above for R=La reveal a transition from a FM (for R=La,Sm) to the E*-type magnetic structure (for smaller rare-earth ions R=Y) \[16\]. RNMO with R=Sm, Y are found to be insulators with electronic structures very close to that of LNMO. We show in Fig. \[1b\] the spin resolved DOS of YNMO in the E*-type magnetic structure. Small differences are found in the values of the band gaps and magnetic moments at Ni and Mn sites between the considered magnetic structures in all RNMO studied in this work. The magnetism is governed by the superexchange interactions due to the Hund’s rule and energy gain allows virtual hopping of parallel spins and forbids anti-aligned spins between half-filled Ni-c$_g$ and empty Mn-c$_g$ orbitals as expected in an extended Kugel-Khomskii model \[17\]. The trend of the exchange parameters with changing R is reported in Table \[1] In-plane exchange interactions between Mn sites are negligible compared to Ni sites. The ratio between the antiferromagnetic next-nearest-neighbour (NNN), $J_{NNN}^{\parallel}$($\parallel$Ni-Mn) and FM nearest-neighbour (NN) $J_{NN}^{\parallel}$($\parallel$Ni-Mn) increases and explains the stabilization of E*-type magnetic structure: a frustrated $\uparrow$-$\uparrow$-$\downarrow$ Ising–like spin chain in ab planes \[1, 19\]. Magnetic couplings changed by intercalation of rare earth with smaller ionic radius gives the possibility to achieve a polar state in RNMO. We recall that the E-type magnetic structure is known to produce large polarization along the short b axis due to the noncentrosymmetric collinear spin arrangement which breaks the inversion symmetry in RMnO$_3$ and RNiO$_3$ \[1, 20, 21, 22\].

In order to understand the transition from the FM to the E*-type magnetic state at a more microscopic level, we analyze the following two-band model Hamiltonian for the double perovskites:

$$H = -\sum_{(ij)\sigma} \epsilon_{i\sigma} c_{i\sigma}^\dagger c_{j\sigma} + H.c. + \sum_i e_i n_i$$

$$\quad + U \sum_{i,\alpha} n_{i\alpha\uparrow} n_{i\alpha\downarrow} + (U' + J_H) \sum_i n_{i\alpha\uparrow} n_{i\beta\downarrow} + n_{i\beta\downarrow} n_{i\alpha\uparrow}$$

$$\quad + (U' - J_H) \sum_i n_{i\alpha\uparrow} n_{i\beta\downarrow} + n_{i\beta\downarrow} n_{i\alpha\uparrow} - J_H \sum_{i\neq i'} S_i \cdot \sigma_i$$

$$\quad + \lambda \sum_i (Q_{xi} t_{xi} + Q_{yi} t_{yi} + Q_{bi} n_i) + H_{el}$$

(1)

Here, $c_{i\sigma}$ and $c_{i\sigma}^\dagger$ are annihilation and creation operators for electrons with spin $\sigma$ in the $e_g$ orbital $\alpha \in \{x^2 - y^2(a), 3z^2 - r^2(b)\}$. $t_{(ij)}$ denote the hopping amplitudes between the two $e_g$ orbitals on NN and NNN sites. The NN Ni-Mn hopping is given by \[22\]:

$$t_{11}^1 = t_{11}^2 = t_{22} = t_{12} = t_{21} = t_{23} = t_{31} = t_{32} = t_{33} = t = t/\sqrt{3},$$

$$t_{13} = t_{23} = t_{33} = t/\sqrt{3},$$

where $x$ and $y$ mark the spatial directions. The NNN hoppings are parameterized by $t'$ such that $t_{iNNN}^\alpha = t' t_{NN}^\alpha$ \[24\]. $e_i$ denotes the on-site energy, and, guided by the electronic structure shown in Fig.\[1\] we set $e_i(Mn/Ni) = \pm \Delta$. $J_H$ denotes the Hund’s rule coupling between the $e_g$ electrons and $U'$ ($U$) is inter (intra)-band Hubbard repulsion with $U = U' + 2J_H$. Since the Mn sites have a half-filled t$_{2g}$ level, an additional Hund’s rule coupling between the Mn-t$_{2g}$ and the Mn-c$_g$ is included. The $\sigma_i$ denotes the electronic spin operator defined as $\sigma_i^z = \sum_\alpha \sigma_i^\alpha c_{i\alpha\uparrow}^\dagger \sigma c_{i\alpha\downarrow}$, where $\Gamma^\mu$ are the Pauli matrices. $\lambda$ denotes the strength of the electron-lattice coupling. $Q_{xi}, Q_{yi}$ are the Jahn-Teller (JT) distortions which are very weak compared to the breathing mode (BM) distortions $Q_{bi}$. The $\tau_{xi} = \sum_\sigma (c_{i\sigma\uparrow} c_{i\sigma\downarrow} + c_{i\sigma\downarrow} c_{i\sigma\uparrow})$ and
\[ \tau_{xz} = \sum_{\sigma} (c_{i\alpha}^\dagger c_{i\sigma} - c_{i\beta}^\dagger c_{i\sigma}) \] are the orbital pseudospin operators for the \( e_g \) orbitals, and the elastic energy for the distortions is included as \( H_{el} = (1/2)(Q_{xz}^2 + Q_{yz}^2 + Q_{zz}^2) \).

Any deviation from collinear spin arrangements is neglected.

We identify the key parameters of the model using inputs from DFT results. An important feature from DFT calculations is the increase in the relative strength of the NNN respect to the NN interactions as \( R \) changes from La to Y (cfr Table I). Therefore we focus on this variation, keeping the other model parameters fixed to reasonable values guided by the DFT results [2]. A staggered pattern of the BM distortions with \( Q_{b} = Q_{c} e^{i(\pi/2) x} \), is assumed following the DFT results discussed earlier. A weak JT distortion is also considered in order to test the robustness of the results. We analyze the model Hamiltonian by employing a Hartree-Fock decoupling of the interaction terms; replacing \( n_{i\alpha} n_{i\alpha}' \) by \( \langle n_{i\alpha} n_{i\alpha}' \rangle + n_{i\alpha} \langle n_{i\alpha}' \rangle - \langle n_{i\alpha} \rangle \langle n_{i\alpha}' \rangle \), etc. The resulting model is solved self-consistently by iterative numerical diagonalization on a two-dimensional Ni-Mn square lattice starting from different possible magnetic states, and the energies of the converged states are compared to find the groundstate. In Fig. 2 we show the total energy per lattice site as a function of the ratio \( t' \) between the NNN and the NN hopping strengths. Panel (a) corresponds to the absence of JT distortions while weak JT distortions are present for the results in panel (b). The figure demonstrates that it is indeed possible to drive a transition from a ferromagnetic to an E\(^{+}\)-type state by increasing the NNN hopping parameter. JT distortions work in favor of the E\(^{+}\)-type state as the \( t' \) required for the FM to E\(^{+}\)-type transition reduces upon increasing \( Q_x \) (See Fig. 2).

Using the Berry-phase (BP) approach we evaluate the first-principles electric polarization \( P_{ele} \) for YNMO. The purely electronic contribution to polarization, \( P_{ele} \), can be calculated by imposing the E\(^{+}\)-type magnetic structure in the centrosymmetric crystal structure with \( P2_1/n \) symmetry, leading to \( P_{ele} = 0.75 \mu C/cm^2 \) along the \( b \) axis. The checkerboard pattern due to Ni\(^{2+}\) and Mn\(^{4+}\) valence in the monoclinic \( P2_1/n \) crystal structure leads to the BM distortions of the NiO\(_3\) and MnO\(_3\) octahedra, which contain three inequivalent oxygen atoms (O\(_1\) out of plane and O\(_2\), O\(_3\) in plane) with corresponding Ni-O-Mn (Ni-O\(_2\)-Mn and Ni-O\(_3\)-Mn) angles differing slightly due to the monoclinic distortion of the unit cell (see Fig. 3a). The E\(^{+}\)-type magnetic order further lowers the crystal symmetry to \( P2_1 \). The magnetic order couples to the lattice and influences the ionic positions and the electronic charge distribution, leading to a decrease in the electronic contribution with respect to the purely electronic term calculated for the centrosymmetric crystal structure. However, the total polarization increases with respect to the centrosymmetric crystal structure due to the ionic contribution: \( P_{Y,N,M,O} = 2.50 \mu C/cm^2 \) (\( P_{ele} = 0.51 \mu C/cm^2 \), \( P_{ionic} = 1.99 \mu C/cm^2 \)).

The exchange energy in the \( P2_1 \) symmetry is minimized: (i) by increasing (decreasing) the distance between \( [\uparrow \downarrow] \) (\( [\downarrow \uparrow] \)) along the \( [\downarrow \uparrow \downarrow] \) spin chains (see \( d', d'' \) in Fig. 3b), which are identical in the original \( P2_1/n \) symmetry (see \( d \) in Fig. 3); (ii) by further splitting from a magnetic point of view of the oxygen ions into 4 inequivalent sites (see Ni-O\(_2\)-Mn, Ni-O\(_{2'}\)-Mn and Ni-O\(_{3}\)-Mn, Ni-O\(_{3'}\)-Mn in Fig. 3b)). The inequivalent oxygen atoms O\(_{2'}\), O\(_{2''}\) and O\(_{3'}\), O\(_{3''}\) are charge-polarized with local dipole moments leading to a net polarization developing along the \( b \) axis. The \( (2,2) \) components of Born effective charges (BEC) are consistent with the inequivalency of oxygen sites: \( Z_{O_{2'}} = -2.87 \) e, \( Z_{O_{2''}} = -2.0 \) e, \( Z_{O_{3'}} = -3.65 \) e, \( Z_{O_{3''}} = -2.76 \) e (for the labelling of the oxygen sites see Fig. 3). Within the so-called point charge model...
(PCM) $P_{\text{NMO}}^{\text{PCM}}=1.64 \mu C/cm^2$, i.e. very close to the one calculated by DFT, confirming that the electronic rearrangement of the charge due to the symmetry breaking is small. Finally, we demonstrate using the model Hamiltonian that an external electric field can induce a magnetic transition in this system. The main effect of an external electric field is to change the on-site energies of the oxygen, which enter in deriving the hopping parameters used in the model. To leading order the hoppings between Mn- and Ni-d via the O-p orbitals are $\propto t_{pd}^{\delta t}/\Delta_{pd}$. Due to the inequivalence of bridging oxygens, $\delta t_{Oy}$ and $\delta t_{Oz}$, in Fig. 3, an external electric field makes $\Delta_{pd}$ and hence the d-d hopping parameters staggered. We use a parameter $\delta t$ as a measure of this modulation, such that the hopping in both x and y direction are spatially staggered $(1 \pm \delta t) t_{\alpha\beta}^{NN}$. Presence of an electric field (modelled as parameter $\delta t$) leads to a change in the magnetic ground-state of the system from a FM to the E*-type, as seen in Fig. 2. Fig. 2 shows the discontinuous change in the total magnetization and the gap in the DOS across this transition. The jump observed in the magnitude of the gap is consistent with the DFT values for the two magnetic phases (see fig. 1).

In conclusion, we have performed density functional theory and model calculations to elucidate the possibility to find novel multiferroics in rare-earths $R_2\text{NiMnO}_6$ double-perovskites. The magnetic state changes from a FM (R=La) to an E*-type (R=Y); the later being well known to assist in ferroelectricity. Calculations on a two-band model combined with inputs from DFT calculations describe this magnetic transition. $Y_2\text{NiMnO}_6$ is shown to be polar in its magnetic ground state with an intrinsic polarization comparable with other magnetically-driven ferroelectrics [26, 27, 28, 29]. We suggest experimental investigations to test our theoretical predictions. We further show that an external electric field can change the magnetic ordering from FM to E*-type leading to a flip from a non-polar state with finite magnetization to a polar state with zero net magnetic moment: a major effect that is of interest for electronic devices.
