Two-dimensional lead halide perovskites are promising materials for optoelectronics due to the tunability of their properties with the number of lead halide layers and the choice of an organic spacer. Physical understanding of the rational design of materials primarily requires knowledge of crystal structure. 2D lead halide perovskites are usually prepared in the form of films complicating the experimental determination of structure. To enable theoretical studies of experimentally unsolvable structures as well as high-throughput virtual screening, we present an algorithm for crystal structure prediction of lead halide perovskites. Using automatically prepared classical potential we show that our algorithm enables fast access to a structure that can be used for further first-principles studies.

I. INTRODUCTION

In recent years, metal halide perovskites (MHPs) have proven to be promising candidates for the future materials of choice for manufacturing light-emitting diodes (LEDs) and solar cells.[1, 2] A subclass of MHPs of particular interest for LED applications are the (quasi-) 2D layered perovskites (Q2DPs) due to larger exciton binding energies, improved stability, and wider tunability of properties compared to 3D perovskites.[3] Particularly, the Ruddlesden-Popper- and Dion-Jacobson MHP phases have gained significant attraction.[4, 5] The general chemical formula of Ruddlesden-Popper perovskites (RPPs) is $R_nA_{n-1}B_nX_{3n+1}$, where $R^+$ is a large amine spacer cation, $A^+$ is a smaller organic cation or Cs $^{+}$, $B^{2+}$ is a divalent metal cation, $X^-$ is a halide anion and $n$ is the number of layers of $BX_6$ octahedra separated by a bilayer of $R^+$ spacer cations (3D perovskite $ABX_3$ is obtained in the limit $n \to \infty$). Similarly, the chemical formula of Dion-Jacobson perovskites (DJP) is $RA_{n-1}B_3X_{3n+1}$, with the difference compared to RPPs being that $R^{2+}$ is a $\text{diammonium}$ cation. This generality of composition offers a great variety of possibilities in choosing $n$ as well as the particular chemicals involved in the synthesis of the layered perovskites, allowing for the characteristic wide tunability of the RPP and DJP physical properties.[3]

Knowledge of the crystal structure of a material is the starting point for understanding its physical properties. Despite constant advances in methodologies[6–9], crystal structure determination from powder diffraction data cannot be yet considered a trivial task because the information from 3D reciprocal space collapses into its 1D projection. Although not as straightforward as the structure solution from single crystals, a huge number of crystalline phases have been successfully solved from the powder diffraction data over the years[10]. On the other hand, when the sample is prepared in the form of a thin film, as almost always is the case in Q2DP-based LED/solar cell research, the determination of structure becomes close to impossible not only due to the strong influence of crystalline texture on the diffracted intensities but also due to the limited and inadequate methodologies. There have been some rare attempts to utilize a grazing incidence X-ray diffraction (GI-XRD) with molecular modeling aiming to determine purely organic structures prepared in the form of thin film[11] but on the practical side, the implementation in everyday laboratory work is restricted due to the requirement that data must be collected using synchrotron radiation. Even if the equipment is readily accessible, due to currently underdeveloped methodology that would properly deal with texture-related issues of thin films, such an approach certainly is not efficient enough to elucidate the immense number of novel Q2DP structures that emerge on the daily basis. Considering the inability to solve the structures from the thin film diffraction data, one way to deal with unknown structures in Q2DP films would be to prepare them in the form of a single crystal or powders. However, there are experimental difficulties when growing materials in the form of a single crystal[12], for example, due to limitations in the stability. In this scenario, many structures of large technological potential remain unknown.

Moreover, it would be greatly valuable to know the structure even before the materials are synthesized. It is, therefore, desirable to use a computational tool to find, understand and predict stable Q2DP crystal structures as well as their physical properties. Different computational approaches have been proposed to explore the possibility of formation of various 3D perovskites[13–15]. Similar computational explorations of Q2DPs have been scarce[16, 17] and did not aim to find the global minimum energy structure, most likely due to the prohibitively vast compositional phase space and large system sizes.

Generally, density functional theory (DFT) is utilized abundantly due to its well-known good balance between accuracy and low computational cost. However, in the case of Q2DPs, the approach to crystal structure predic-
tion via DFT suffers from several drawbacks. Optimizing an initial-guess structure using a local structural relaxation algorithm gives no guarantee that the final structure is the global minimum. This may be resolved by exploring a sufficiently large part of the potential energy surface (PES), but this is computationally unfeasible, as in the case of Q2DPs unit cells may contain several hundreds of atoms, giving rise to complex PES’s. \cite{15}

In this work, we introduce a workflow for predicting candidate Q2DP crystal structures using classical model potentials combined with DFT. The potentials are constructed in an automated fashion and then employed to find a global minimum structure via minima hopping algorithm in the vein of Goedecker \cite{19}, Amsler and Goedecker \cite{20} and Peterson \cite{21}. In this work, we will refer to the developed algorithm as GO-MHALP (Global Optimization via Minima Hopping Algorithm for Layered Perovskites). We aim to develop a method which is generalizable, but specialized to work for Q2DP structures with well defined general structural features, such as the alternating organic/inorganic layered structure. Therefore, we expect to start from structures not too far from a global minimum so that minima-hopping is a well suited technique, as opposed to methods which work well when starting far away from the global minimum, such as particle swarm optimization \cite{22} or genetic algorithms \cite{23}. Our method works in principle for any candidate Q2DP whose $R^+/R^{2+}$ and $A^+$ compounds are organic cations consisting of $N$, $C$ and $H$ and whose inorganic perovskite octahedra are PbBr$_6$. The complete methodology is described in section II while validations of the model on RPPs containing BA (butylammonium) and MA (methylammonium) and a DJP containing 4AMP (4-(aminomethyl)-piperidinium) are presented in section III. Additionally, we have extended the method to predict an unknown Q2DP structure containing mixed-halide perovskite octahedra PbBr$_3$I$_3$ \cite{24}.

II. METHODOLOGY

In the following two subsections, we describe the procedure of generating structures and the accompanying classical potentials which are used as inputs for GO-MHALP. A visual aid in the form of a flowchart of the procedure can be viewed in Fig. 2. In the third subsection, we describe the GO-MHALP algorithm itself with an accompanying flowchart in Fig. 3.

A. Initial structures generation

One of the advantages of structure prediction using global optimization algorithms is that the final set of found structures should not depend strongly on the starting structure inputted to the algorithm. However, in the particular case of MH, it is necessary to start from a region in configuration space for which the potential has a physical meaning, i.e. in our case, the starting structure should resemble a Q2DP. To this end, we developed an automatized procedure for the generation of idealized Q2DP structures for a given $R$ molecule.

We investigated three types of initially tetragonal cell geometries with parallel or offset interlayer configurations, making a total of six different types of input structures as shown in Fig. 1. These cell types were chosen because known Q2DP structures often form these geometries \cite{25}. Furthermore, in the various cell types, the supercells can be rearranged to produce equivalent structures, providing an additional check of the independence of the found global minimum on the initial guess structure. The parallel and offset structures are related by a layer shift, while the $1 \times 1$ and $\sqrt{2} \times \sqrt{2}$ are subcells of the $2 \times 2$ cell type.

We prepared multiple template structures by arranging the inorganic layers in ideal aforementioned configurations and (for $n > 1$) placing MA molecules at the centers of inorganic cages. The $R^+/R^{2+}$ organic cations are first added to the template structures so that the NH$_3$ groups of the cations are placed approximately at the centers of the inorganic pockets. For RPPs, the cations are reoriented in such a way so that the vector from the N atom towards the respective cation’s center of mass points in a predefined direction towards the neighboring inorganic sheet. The interlayer spacing between the inorganic sheets can be adjusted as needed to accommodate spacers of various lengths. We advise the reader to see the code in [\texttt{X}] (Data Availability) as well as Section 3. in Supplemental Material for further details. All generated initial guess structures are given in the Supplemental Material in CIF format as well.

Since we are ultimately interested in global structure optimizations in which the starting structure should not be of decisive importance, this simple way of generating structures works very well for our intentions since it is automatic and fast.

B. Construction of classical potentials

Following previous work \cite{26, 30}, and in particular the idea behind MAPI family of potential developed by Mattioni et al. \cite{28, 29}, we undertake an approach where the total classical potential is modeled as a sum of i) non-bonding potential that depends only on the interatomic distances with only two-body terms taken into account and ii) a bonding potential including bonds, dihedrals, and angles as described by GAFF \cite{31}, a generalization of the AMBER \cite{32} force field.

Denoting the list of positions of the nuclei with $\{R\} := (R_1, R_2, \ldots , R_N)$, the general form of the total potential energy can be written as

$$U(\{R\}) = \frac{1}{2} \sum_{i,j} N U_{ij}(R_{ij}) + U^{\text{bonding}},$$  \hspace{1cm} (1)
where $R_{ij} := |R_i - R_j|$. As in all effective-potential approaches, the electronic degrees of freedom do not enter the calculation explicitly but are rather absorbed into the effective interactions of the nuclei.\[33\]

$U_{ij}$ is separated into three parts, dealing with the nonbonding inorganic-inorganic, inorganic-organic and organic-organic interatomic interactions respectively:

$$U_{ij} = U_{iij} + U_{ij}^{IO} + U_{ij}^{OO}.$$  \hspace{1cm} (2)

The explicit form of the inorganic-inorganic interaction is

$$U_{iij}^{II}(R_{ij}) = A_{ij} \exp\left(-R_{ij}/\rho_{ij}\right) - \frac{c_{ij}}{R_{ij}^6} + \frac{q_i q_j}{4\pi \varepsilon_0 R_{ij}},$$  \hspace{1cm} (3)

where the first two terms comprise the Buckingham potential\[34\] with the first term describing the Pauli repulsion at small nuclei distance and the second term describing the van der Waals interaction with $A_{ij}$, $\rho_{ij}$ and $c_{ij}$ as model parameters. The final term is the Coulomb interaction between two (possibly partial) ionic charges.

The inorganic-organic interaction is modelled as follows:

$$U_{iij}^{IO}(R_{ij}) = A_{ij} \exp\left(-R_{ij}/\rho_{ij}\right) - \frac{c_{ij}}{R_{ij}^6} + \frac{q_i q_j}{4\pi \varepsilon_0 R_{ij}},$$  \hspace{1cm} (4)

expressing bonds, angles and dihedrals respectively. $R_{ij}$ are two-body distances, $\theta_{ijk}$ are three-body angles, and $\phi_{ijkl}$ are four-body dihedrals while the other factors are GAFF parameters. The main advantage of the Gaff force field is its capability to describe a very large number of organic molecules with an acceptable level of accuracy. Besides, its standard working frame allows in principle an automatic atom type assignment for any given organic molecules in its (reliably) relaxed geometry.

The idea of GO-MHALP is to have a general and flexible tool that can be applied to any organic molecule R in a candidate Q2DP structure. If the particular molecule is not found in the local database of organic cations the potential can be generated in the very first step provided a starting geometry along with the GAFF philosophy. Shortly, to obtain GAFF parameters the geometry of the $R^+$ molecule is optimized using the Gaussian program with the B3LYP hybrid DFT functional and 6-311G* basis set.\[41–43\] Consistently with previous work\[28\], the electrostatic potential (ESP) of the optimized isolated cation with +1 total charge is obtained via the B97-3p and the Def2TZVP basis set. Partial atomic charges are then obtained by directly fitting this ab initio electrostatic potential (ESP) using the restrained electrostatic potential (RESP) method as implemented in the Antechamber program from the Amber16 suite.\[51, 52\] Complete molecular topology and GAFF parameters are generated and translated to

\[5\]

\[\begin{align*}
U_{ij}^{IO}(R_{ij}) &= 4\epsilon_{ij}\left[\left(\frac{\sigma_{ij}}{R_{ij}}\right)^6 + \left(\frac{\sigma_{ij}}{R_{ij}}\right)^{12}\right] + \frac{q_i q_j}{4\pi \varepsilon_0 R_{ij}}.
\end{align*}\]
FIG. 2. Flowchart of the procedure of generating an input LAMMPS file containing information on the structure and interatomic interactions of a Q2DP.

LAMMPS format and added to the local database of organic cations.

The parameters for the C − C, N − N and H − H non-bonding Lennard-Jones interactions are obtained from GAFF parametrization as described above. As for the nonbonding parameters concerning Pb − Pb and Br − Br interactions, the values of these are taken to be the same as the ones obtained in Hata et al. for MAPbBr$_3$, barring the charges $q_i$, which for organic molecules we set to the partial charges obtained by RESP fitting and for the atoms comprising the inorganic perovskite structure we set $q_{PB} = +2$ and $q_{Br} = -1$. The reason for this is that the charges in Hata et al. were set by rescaling of charges obtained by Mattoni et al. for MAPbI$_3$ and in both of these works the obtained charges of the inorganic lattice PbBr$_3$ do not sum up to 1. In Mattoni et al. system neutrality was then ensured by refitting the charge parameters of the whole model (including MA) to data obtained via DFT. For this work, by setting integer charges we avoid the need for expensive DFT calculations and refitting procedures, thus greatly increasing the transferability of this method for construction of classical potentials.

A benchmark of the accuracy of the potentials may be found in the Supplemental Material.

C. Minima hopping

Minima hopping (MH) is an efficient and simple global optimization method first developed by Goedecker. The general idea is to alternate between molecular dynamics (MD) simulations and local structure optimizations (relaxations) after which some criteria are used to determine whether the optimized structure will be accepted as a newfound local minimum. A system may gain enough kinetic energy during MD to overcome a potential barrier and in this way, a complex PES may be traversed to arrive at different potential energy basins.

The original MH method conceived by Goedecker concerned only nonperiodic systems and therefore employed only local optimizations of atomic positions. However, the ground state of a crystalline system is fully determined not only by atomic positions but also by the unit cell parameters. Therefore, by using variable cell shape MD, Amsler and Goedecker generalized the MH method to be functional for periodic systems as well. Another variant of MH, dubbed constrained minima hopping, was developed by Peterson. Peterson introduced a simple constraint, based on Hooke’s law, in order to prevent dissociation of molecules adsorbed on a surface during the MD portion of MH, thereby effectively reducing the con-
In this work, we combine and modify the approaches introduced above to develop an MH algorithm suitable for Q2DP global structure optimization: GO-MHALP. We simulate MD in the isothermal-isobaric (NPT) ensemble and optimize the unit cell as well as atomic positions during local optimizations. Additionally, we developed a new scheme for detailed exploration of local energy basins and on-the-fly selection of the lowest energy structures found in them.

We implemented our algorithm based on an MH algorithm already existing within the ASE\cite{Plimpton89} package using the LAMMPSlib interface to read in the classical potential described in section \ref{sec:potentials}. Now we present an outline of the algorithm. A list of initial parameters, their descriptions and values can found in Table \ref{tab:initial_params}. The input structure is fed into the algorithm and its cell and atomic positions are optimized. This optimized structure is the first entry in the list of found local minima. The initial optimization is performed with a looser force convergence threshold than following optimizations to avoid a long optimization step since the initial structure may be far away from a local minimum. For ease of writing, from now on we will label the physical properties of the entries in the list of found local minima with the subscript $i$, where $i = 1, \ldots, N$ so that $N$ labels the last found minimum. At this point, there is only one structure in the list of found minima, i.e. $N = 1$.

An NPT\cite{Thompson2002, Allen1987, Eastwood2010} molecular dynamics simulation is performed starting from the locally optimized structure at temperature $T = T_0$ and with other parameter values being as listed in Table \ref{tab:initial_params}. The values of the NPT related parameters were chosen to ensure that the molecular dynamics is long enough for the system to completely thermalize. Generally, the starting NPT configuration is the last (N-th) minimum in the list of found minima and $T$ varies during GO-MHALP as described below. Ions are given random initial velocities corresponding to a Maxwell-Boltzmann distribution of temperature $T$. NPT is stopped after $md_{\text{min}}$ local minima have been passed over with one pass counted if a sequence of potential energies calculated at each MD step ends with two downward points followed by two upward points.

The atomic positions and cell parameters of the last configuration obtained by NPT dynamics are optimized. We label the physical properties of this candidate structure with the subscript $c$. After optimization, energy and structure similarity checks are performed to determine whether the candidate structure will be added to the list of local minima. Firstly, $E_c$ is compared to $E_N$; if $E_c > E_N + E_{\text{diff}}$, the structure is discarded as being too high in energy, NPT temperature is increased, i.e.
$T \rightarrow \beta T$ and a new NPT/optimization cycle is started from the $N$-th minimum in the list of found minima. Otherwise, a structure similarity check is performed. For structure comparison we use Oganov fingerprints\cite{OG02,OG03} which were first used in the context of MH by Amasler and Goedecker\cite{AM08}. With this method, for every structure a unique "fingerprint" may be calculated and represented as a matrix in an abstract vector space. The components of the matrix are sums of Gaussian-smeared delta functions:

$$F_{AB}(R) = \sum_{A_i, B_i} \frac{\delta(R - R_{kl})}{4\pi R_{kl}^2 N_{A_i}N_{B_i}} - 1,$$

where the sum runs over all pairs of atoms of types $A$ and $B$ found within the cutoff distance $R_{kl} < R_c$, with $N_A$ and $N_B$ being the number of atoms of the respective type $A$ and $B$ in the unit cell and $V$ being the unit cell volume. Each fingerprint component $F_{AB}(R)$ is discretized into bins of width $\Delta$ so it can be represented as a vector with the $m$-th vector coordinate being the value of the fingerprint component $F_{AB}(m)$. A cosine distance $\chi_{i,j}$ may then be defined as a measure of dissimilarity of structures $i$ and $j$:

$$\chi_{i,j} = \frac{1}{2} \left( 1 - \sum_{AB} \sum_m F_{AB}(m) F_{AB}^j(m) w_{AB} \right)$$

where the importance weight $w_{AB}$ is defined as

$$w_{AB} = \frac{N_A N_B}{\sum_{cel} N_A N_B}$$

and $W^j$ is the norm

$$W^j = \sum_{AB} \sum_m [F_{AB}(m)]^2 w_{AB}.$$ 

To reduce noise, we excluded hydrogen atoms from the calculation of cosine distances. The cosine distance $\chi_{c,i}$ is calculated as a measure of dissimilarity between the candidate structure and a structure $i$ from the list of found local minima. If $\chi_{c,i} > \chi^0$ for every $i$ and the threshold parameter $\chi^0$, the candidate structure is added to the local minima list and the NPT temperature is reset to the initial temperature $T_0$. Otherwise, the candidate structure is considered not to be a unique minimum and the NPT temperature is increased, i.e. $T \rightarrow \beta T$. The candidate structure replaces the $N$-th minimum if the following three conditions are met: $E_c < E_N$, $\min\{\chi_{c,1}, \ldots, \chi_{c,N}\} = \chi_{c,N}$ and $\chi_{c,N-1} > \chi^0$. With this replacement scheme and the choice of parameters as listed in Table 1, we found that the algorithm correctly explores local potential energy basins while preserving structural dissimilarity of the found minima.

This concludes a complete MH cycle in our GO-MHALP frame. If the number of cycles is less than the given MH$_{\text{steps}}$ parameter the algorithm will start a new NPT simulation from the last found minimum and otherwise the algorithm stops.

### D. DFT calculations

On specific structures (see below), DFT relaxations were additionally performed in order to validate and refine the results. All DFT relaxations were performed using the plane-wave basis set code Quantum Espresso\cite{QE09,QE11} with the plane-wave basis set cutoff being 816 eV. GBRV pseudopotentials\cite{GBRV97} were employed together with the vdW-DF-cx exchange-correlation functional\cite{DHF09}. A Monkhorst-Pack k-point mesh\cite{MP76} with a density of 5 Å was used for Brillouin zone integration. The atomic positions and the unit cell parameters were relaxed until the pressure, the forces on each atom and the total energy change were smaller than 0.5 kbar, 0.02 eV Å$^{-1}$ and 1 meV, respectively.

### E. Similarity measures of simulated powder XRD patterns

In order to assess the validity of the predicted structures with our protocol, we quantified the similarity of structures obtained with GO-MHALP to structures solved from single-crystal XRD data by simulating their powder XRD (PXRD) patterns and calculating a similarity measure based on cross-correlation functions\cite{CC01,CC02} as implemented in the PyXtal\cite{Xtal} Python library. Explicitly, the similarity measure $s_{12}$ of two powder diagrams $y_1(\theta)$ and $y_2(\theta)$, invariant against scaling of the PXRD intensities, is calculated as

$$s_{12} = \frac{\int w(r)c_{12}(r) dr}{\left[ \int w(r)c_{11}(r) dr \int w(r)c_{22}(r) dr \right]^{1/2}}$$

where $c_{12}$ is the cross-correlation function:

$$c_{12}(r) = \int y_1(\theta)y_2(\theta + r) d\theta$$

with the auto-correlation functions $c_{11}$ and $c_{22}$ defined analogously. We used the cosine weighting function:

$$w(r) = \begin{cases} 0.5 \cos(\pi r/l) + 1, & |r| < l \\ 0, & |r| > l \end{cases}$$

with the cutoff $l = 1.0^\circ$. The similarity measure adopts values between 0 and 1, where $s_{12} = 1$ corresponds to identical PXRDs. An example of a comparison of PXRDs simulated from an experimentally solved structure and a minimum obtained with GO-MHALP is shown in Figure 4.

### F. Potentials for iodine and mixed halide systems

GO-MHALP is a general procedure which can in principle, given a suitable classical potential, be used for any systems. E.g., classical potentials for Q2DPs containing
iodine instead of bromide can be constructed in a completely analogous manner as described in Section IIB but using the parameters for MAPbI$_3$[28, 30]. As detailed in an another work[24], we employed GO-MHALP to predict a mixed halide structure. We use the Berthelot rule to calculate the Buckingham parameters for Pb−Pb and Br−I interactions:

$$A_{\text{mixed}}^{\text{mixed}} = \sqrt{A_{\text{Br}}^{\text{Br}}A_{\text{I}}^{\text{I}}}$$

where $A_{\text{Br}}$ and $A_{\text{I}}$ denote Buckingham parameters used for pure halide structures and $A_{\text{mixed}}^{\text{mixed}}$ are Buckingham parameters used for the mixed halide structures.

III. RESULTS AND DISCUSSION

We first validate GO-MHALP on the well known case of $R^+ = \text{BA}^+$ (butylammonium) cation as spacer. Both BA$_2$PbBr$_4$ and BA$_2$MAPb$_2$Br$_7$ have been successfully prepared and their crystal structures were solved.[68, 69] Following the tests on RPPs with BA we continue the validation of GO-MHALP on a DJP structure containing 4AMP (4-(aminomethyl)-piperidinium).[3] We use the experimentally obtained structures as reference points for validation of GO-MHALP predictions. Radial distribution functions and simulated PXRD patterns for relevant (predicted and experimental) structures may be found in the Supplementary Information. CIF files for these structures are given the Supplementary Data.

Finally, we show performance of GO-MHALP to predict a structure of a mixed-halide Q2DP $t$-BA$_2$PbBr$_2$I$_2$. This structure was experimentally solved after the prediction with GO-MHALP.
A. $\text{BA}_2\text{PbBr}_4$

We first applied GO-MHALP to $\text{BA}_2\text{PbBr}_4$ RPP. The six types of unit cells described in IIA were used as inputs. A summary of a GO-MHALP run is shown in Fig. 6. First, the top panel shows that during MD the system is well thermalized to the set thermostat temperature. Potential energy barriers are overcome by gradually increasing the temperature and newfound minima are accepted upon entrance into a local energy basin. After each restart of the NPT temperature to $T_0$, GO-MHALP explores the surrounding configuration space in detail and the replacement scheme described in section IIC selects the lowest energy structure found in a basin. The global minimum for this run, i.e. the lowest energy local minimum, is found in a distinct basin that lies very close in energy to the experimentally solved structure whose atomic positions and cell parameters were optimized with the classical potential (dashed line). This is an indication that the global minimum of the model potential is connected to the true (experimental) global minimum by a local optimization, a point to which we will return below.

For a complete test and validation of GO-MHALP, we calculated similarity measures of PXRDS between the experimental structure and

a) each of the final minima predicted with six GO-MHALP runs for the six different cell types;

b) experimental structure, relaxed with the classical potential;

c) experimental structure, relaxed with DFT;

d) lowest energy (global) minimum found with GO-MHALP, relaxed with DFT;

e) the GO-MHALP initial structure from which the global minimum was found, relaxed with DFT.

Similarity measures a) and b) are plotted against classical potential energies in Fig. 7 as scatter points and similarity measures b)-e) are plotted as vertical dashed lines. In particular, the line corresponding to case (b) sets the practical limit of the similarity measure that can be reached by this version of GO-MHALP. First of all, we can notice that the energies of the best (lowest energy) minima of $1 \times 1$ cell types are noticeably higher than the larger cell types, meaning that GO-MHALP predicts that $1 \times 1$ unit cells are too small to capture all experimentally realized degrees of freedom, which is indeed correct as the experimental structure of the $\sqrt{2} \times \sqrt{2}$ type. The best minima of $\sqrt{2} \times \sqrt{2}$ and $2 \times 2$ cell types cluster nearby the experimental structure relaxed with the classical potential (marked with a star) regardless of the initially parallel or offset interlayers, showing that in these cases GO-MHALP reliably finds the global minimum of the potential regardless of the details of the input structures. While GO-MHALP
finds the experimental structure relaxed with the classical potential, agreement of these structures with the true experimental structure is not completely satisfactory (similarity of around 0.7). On the other hand, relaxing the experimental structure with DFT achieves a similarity of 0.95. Clearly, GO-MHALP has the ability to find the global minimum, but the model potential should be improved.

The global minimum itself is found for the initially O: 2×2 cell type, with the best P: 2×2 and the $\sqrt{2} \times \sqrt{2}$ minima being slightly higher in energy. O: 2×2 input structure after initial relaxation shows already a good similarity of 0.515 which is further improved by GO-MHALP to score 0.635 at the global minimum. Relaxing the global minimum with DFT significantly improves this value to a similarity measure of 0.915. This final step suggests that an extra DFT relaxation of the global minimum found by GO-MHALP renders final structures that can be highly accurate. The small inset in Figure 7 depicts how the PES exploration works in GO-MHALP in the case of the O: $\sqrt{2} \times \sqrt{2}$ unit cell. The system goes through a couple of minima before locating the basin containing the global minimum.

B. BA$_2$MAPb$_2$Br$_7$

We continue the validation of GO-MHALP on a similar $n = 2$ RPP: BA$_2$MAPb$_2$Br$_7$. The obtained similarity measures are summarized in Fig. S10. As is the case for BA$_2$PbBr$_4$, the global minimum of the potential is nearby the experimental structure relaxed with the classical potential with a higher similarity measure compared to the $n = 1$ case. A possible rationalization of this fact is that the accuracy of the potential is expected to grow with the number of layers $n$ as the potential is constructed using parameters for a 3D perovskite.

GO-MHALP correctly predicts that BA$_2$MAPb$_2$Br$_7$ crystallizes in the $\sqrt{2} \times \sqrt{2}$ cell type. The low energy region of the PES is not as rich as is the case for BA$_2$PbBr$_4$ and is surrounded by higher potential barriers. This can be seen in Fig. 8: the first local basin that GO-MHALP found was the one containing the global minimum and higher NPT temperatures were needed to overcome basin barriers. The relative flatness of the PES going from the input to the global minimum is the reason why relaxations of input structures, both by using DFT and classical potentials, resulted in structures near the global minimum with an already large similarity measure. Relaxing the found global minimum with DFT again achieves a slightly better similarity (0.940) compared to relaxing
FIG. 10. Similarity measures and (classical) potential energies of (4AMP)PbBr$_4$ starting from the experimental-like $2\sqrt{2} \times \sqrt{2}$ cell type. The vertical dashed lines indicated as X/Y show similarity measures of structures X relaxed with Y level of theory (see text). Different markers indicate different patterns of connection of 4AMP molecules to the inorganic perovskite layer (see text). Diamond (♦) markers indicate the starting GO-MHALP points after initial relaxation. The star (★) marker indicates the similarity measure and energy of the experimental structure relaxed with the classical potential. Energies are shown per formula unit with the zero of the potential energy chosen as the energy of the global GO-MHALP minimum.

C. (4AMP)PbBr$_4$

To validate the GO-MHALP workflow on a Q2DP containing a different spacer, we select the Dion-Jacobson type perovskite (4AMP)PbBr$_4$. 1-(4-Piperidinyl)methanamine (4AMP) structure is shown in Fig. 5. At one molecular end, one nitrogen atom belongs to the aminomethyl unit, while the other is within the piperidinyl ring on the opposite side. In a Dion-Jacobson perovskite, these two nitrogens connect to the inorganic perovskite layers. Therefore, neighbouring organic 4AMP molecules may differently connect to the same layer, i.e. one 4AMP may connect via the aminomethyl unit and its neighbour via the piperidinium unit. To account for this possibility, we considered the following initial configurations:

- (na) non-alternating; i.e. all neighbouring 4AMP molecules connect to a perovskite layer in the same manner;
- (a1) all-alternating; i.e. all neighbouring 4AMP molecules connect to a perovskite layer in the opposite manner;
- (a2) half-alternating; i.e. two neighbouring 4AMP molecules connect to a perovskite layer in the same manner, while the other two connect in the opposite manner.

Note that the configuration (a1) is possible for $\sqrt{2} \times \sqrt{2}$ and $2 \times 2$ cell types, while (a2) is possible only for $2 \times 2$. It
is necessary to explicitly include all these configurations in the initial structures since it is extremely unlikely for the molecules to completely reorient during MD. This gives a total number of 12 types of initial structures for GO-MHALP.

A summary of a GO-MHALP run is shown in Fig. 0. After locating ten Q2DP local minima (including the minimum obtained with initial relaxation), GO-MHALP is unable to find a unique minimum, which results in the MD temperature rising to about 600 K. This high-temperature MD "melts" the inorganic perovskite structure resulting in the final structure losing its Q2DP character. We deem these "melted" types of structures unphysical predictions as the classical potential is, by construction, well-defined only for Q2DPs and we exclude them from following analysis.

The second point to be noted in Fig. 0 is that the energy of the experimentally solved structure relaxed with the classical potential is significantly lower than any of the structures explored by GO-MHALP. The reason for this is that the experimentally resolved structure has more degrees of freedom than the ones describable by configurations in Fig. 0. Specifically, in the notation established in this paper, the experimentally obtained cell is of the $2\sqrt{2} \times \sqrt{2} \times 2$ type.\[70\] This cell type allows for an intricate pattern of alternating 4AMP orientations: along the shorter cell axis, the manner of connection does not change, while it is altered for every second neighbour along the long cell axis.

The summary of GO-MHALP runs for all cell types is shown in Fig. S11. As explained in the last paragraph, all structure types lack the necessary number of degrees of freedom to find the experimental structure relaxed with the classical potential. Relaxing the lowest energy minimum of the O(a2): $2 \times 2$ cell type with DFT actually results in worse similarity (0.715) compared to simply relaxing the initial guess structure with DFT (0.776). However, the energy (as calculated with DFT) of the relaxed O(a2): $2 \times 2$ minimum is significantly lower than the energy of the relaxed initial guess structure (0.15 eV per formula unit), meaning that, while it is not close to the experimental structure in a sense, it is a lower energy local minimum.

To allow GO-MHALP to find the true global minimum, we prepared three input structures with the same cell type as the experimental structure by first removing the one redundant inorganic layer from the $2\sqrt{2} \times \sqrt{2} \times 2$ cell type, followed by an extension to a $2\sqrt{2} \times \sqrt{2}$ supercell. We considered three 4AMP configurations:

- nonalternating: all 4AMP molecules connect to the perovskite layer in the same manner;
- alternating: the 4AMP molecules alternate the manner of connection to the perovskite layer along the long cell-axis;
- experimental-like: the manner of connection of the 4AMP molecules to the perovskite layer is alternated for every second neighbour.

The results of the GO-MHALP run with these structure types are shown in Fig. 10. The global minimum of the potential (the experimental structure relaxed with the classical potential) is found exclusively for the experimental-like connection pattern. Relaxing the initial guess structure of the experimental cell type with DFT achieves a similarity of 0.74, while relaxing the found global minimum achieves a remarkable similarity of 0.968, almost perfectly overlapping the similarity of the experimental structure relaxed with DFT.

D. $t$-BA$_2$PbBr$_2$I$_2$

We have employed GO-MHALP to predict a previously unknown Q2DP structure and verified its prediction by single-crystal XRD measurements. We used tert-butyl ammonium ($t$-BA) as the organic spacer. While this is detailed in a separate work [24], we here deepen the discussion of the application of GO-MHALP to that challenging case. The optical measurements indicated that synthesis starting from a one-to-one iodide-bromide stoichiometry results in $t$-BA$_2$PbBr$_2$I$_2$, a crystallized $n = 1$ RP phase, while syntheses starting from pure bromide or pure iodide stoichiometries do not yield Q2DP structures [23]. We confirmed the instability of the pure halide Q2DPs by calculating the formation energies of the global minima found with GO-MHALP as well as by XRD measurements.

To predict the structure of the mixed-halide $t$-BA$_2$PbBr$_2$I$_2$, we prepared three types of input structures for GO-MHALP as shown in Fig. 11 with the corresponding GO-MHALP runs shown in Fig. S12. We see that the minimum corresponding to the experimental structure relaxed with the classical potential is found exclusively starting from the equatorial (axial) bromide (iodine) initial configuration, consistent with the specific halide distribution we found in the structure we resolved experimentally with single-crystal XRD. Relaxing the global minimum with DFT results in a remarkable similarity of 0.967. The relaxed global minimum structure is a local DFT minimum almost isoenergetic to the experimental structure relaxed with DFT (its energy as calculated with DFT is higher by $\approx 4$ meV/f.u.), but it is closer to the experimental structure by $\approx 0.02$ similarity points.

IV. CONCLUSION

In this work, we have introduced a workflow for automatic crystal structure prediction of Q2DP structures. To achieve this, we have developed an automatized initial structure guess and classical potential generation and combined them with a variant of the minima hopping algorithm dubbed GO-MHALP. We tested GO-MHALP on well known Q2DP structures: BA$_2$PbBr$_4$, BA$_2$MAPb$_2$Br$_7$ and (4AMP)PbBr$_4$. We have shown that
the global minimum is reliably found by GO-MHALP
with a weak dependence on the input structure.

The case of (4AMP)PbBr₄ suggests that it is neces-
sary to start from a structure with the minimum neces-
sary number of degrees of freedom. We have also shown
how GO-MHALP can be used to predict the structure
of a mixed-halide Q2DP: t-Ba₂PbBr₂I$_{2}$. We confirmed
that not only the specific halide distribution was correctly
predicted by GO-MHALP, but also that the structural
details were predicted very precisely.[24]

While the accuracy of the classical potential itself can
be significantly improved, within our method it is not
necessary for it to be extremely precise. We have shown
that the sufficient condition for a very accurate predic-
tion is only that the global minimum of the potential is
connected to the DFT global minimum by a DFT local
relaxation. However, the potential should be improved
in general to provide reliable predictions for any Q2DP.

We also note that our approach provides physically re-
alistic predictions at a low computational price. Assum-
ing one evaluation of energy and forces with a classical
potential is $10^{6}$ times faster than a single SCF calcula-
tion, 200 GO-MHALP cycles of 25 ps NPT simulations
take about as long as 5 SCF calculations. This is much
less than the number of SCF calculations performed in
a typical DFT structural relaxation. Therefore, an un-
biased structure prediction may be obtained in less time
than necessary for two DFT structural relaxations. Since
this computational cost is negligible, GO-MHALP may
be further improved by using DFT to relax a larger num-
ber of predicted structures around the found global min-
imum.

Compared to previously available minima hopping al-
gorithms, we implemented several improvements: i) the
MD temperature is restarted after a structurally unique
minimum is found; ii) the replacement scheme, which in
combination with i) ensures detailed exploration of local
PES basins; iii) employment of an NPT ensemble for the
MD part of minima hopping, and iv) inclusion of both cell
and atomic coordinate relaxations. We believe that these
improvements could be employed in structure prediction
problems generally whenever multiple kinds of degrees of
freedom (configurational, conformational, combinatorial,
etc.) render the exploration of PES particularly difficult,
e.g. in soft-matter and molecular crystals.

DATA AVAILABILITY

The complete code for generating initial struc-
tures, corresponding model potentials and running GO-
MHALP is available free of charge at [https://github.
com/ovcarj/classical-RPP/tree/ase2020](https://github.
com/ovcarj/classical-RPP/tree/ase2020). Using this
code all presented data can be regenerated. Derived data
are also available from the corresponding author upon
reasonable request.

See Supplemental Material at [URL will be inserted by
publisher] for a benchmark of the accuracy of the classical
potentials, a detailed technical description of the struc-
ture generation algorithm, calculated radial distribution
functions, simulated powder XRD patterns and plots of
similarity measures versus potential energies. CIF files
of all the initial guess structures and the most relevant
found structures are also given in the Supplemental Ma-
terial.

|----------------|-----------|-----------------------------------------------------------------------------|
| $\chi$ \textsuperscript{0} | 0.005     | Maximum cosine distance between two structures below which they are considered to be the same structure |
| $\Delta$ / Å   | 0.05      | Width of the bins into which the Oganov fingerprint components are discretized |
| $\sigma$ / Å   | 0.1       | Standard deviation of the gaussian smearing of fingerprints                  |
| $N_{\sigma}$    | 5         | Number of standard deviations $\sigma$ at which the gaussian smearing is cut off |
| $R_c$ / Å       | $l_{\min}$ | Cutoff radius in Angstrom for the fingerprints. At every MH step, the shortest cell length $l_{\min}$ is used |

| Parameter      | Value     | Description                                                                 |
|----------------|-----------|-----------------------------------------------------------------------------|
| $R_c$ / Å       | $l_{\min}$ | Cutoff radius in Angstrom for the fingerprints. At every MH step, the shortest cell length $l_{\min}$ is used |

**TABLE I.** List of parameters used in the MH algorithm.
