 Charged-Lepton Flavour Physics

ANDREAS HOECKER\textsuperscript{a,}\textsuperscript{*}

\textsuperscript{a}CERN, Switzerland

Abstract. This writeup of a talk at the 2011 Lepton-Photon symposium in Mumbai, India, summarises recent results in the charged-lepton flavour sector. I review searches for charged-lepton flavour violation, lepton electric dipole moments and flavour-conserving $CP$ violation. I also discuss recent progress in $\tau$-lepton physics and in the Standard Model prediction of the muon anomalous magnetic moment.

1. Introduction

The instability of the scalar sector of the Standard Model (SM) with respect to fermionic and bosonic loop corrections in presence of an ultraviolet cut-off scale has been the driving motivation for the widespread expectation of TeV-scale new physics. Such new physics is in reach for discovery at the LHC which sets the current experimental energy frontier. Clean measurements in the charged-lepton flavour sector can also probe new physics at high scales, in fact, at mass scales up to hundreds of TeV and above, albeit the interpretation of a measurement in terms of mass scales is model-dependent. Such measurements often involve rare processes or small deviations in abundant processes (because they are scale suppressed) and hence require large rates and high precision to be observable. The experiments performing these measurements operate at the intensity and precision frontier. Both, the energy and intensity/precision frontiers are complementary domains of activity in modern particle physics research that must be pursued in common.

Although some deviations between experiment and Standard Model expectation exist in the charged flavour physics sector, none is presently significant enough to demonstrate evidence for new physics. It is nevertheless important to follow up on them. Just as important are the measurements for which, in our ignorance, one would have expected new physics to show up but none has been seen. Indeed, many of the models that have been developed to stabilise the Higgs boson sector, or that suggest alternatives to it, predict new flavour-changing neutral currents, $CP$-violating phases, charged-lepton flavour violation, electric dipole moments, anomalous magnetic moments, contributions to electroweak precision observables, etc. Their non-observation strongly constrains these models, though – apart from very specific cases – does not exclude them. It does, however, affect their naturalness and the searches at the LHC, be they positive or not, will need to be scrutinised in view of the results from the precision measurements.

I review in the following searches for charged-lepton flavour violation, lepton electric dipole moments and flavour-conserving $CP$ violation. I also discuss recent progress in $\tau$-lepton physics and in the Standard Model prediction of the muon anomalous magnetic moment.

2. Charged-lepton flavour violation

Flavour violation involving charged leptons (LFV) belongs to the class of flavour-changing neutral currents (FCNC), which are suppressed at tree level in the SM where they are mediated by $\gamma$ and $Z^0$ bosons, but arise at loop level via weak charged currents mediated by the $W^\pm$ boson. The GIM mechanism further suppresses loop-induced FCNC in the quark sector, so that FCNC effects are generally small in the SM. Rare FCNC processes such as $B^0_s \rightarrow \mu\mu$ or $K^+ \rightarrow \pi^+\nu\bar{\nu}$ (and many others) are therefore sensitive probes for new physics. The former mode is currently actively investigated at the LHC [2, 3], while the latter channel will be studied by the NA62 experiment that is under construction at CERN [4].

Because flavour violation requires mixing between generations, charged LFV exactly vanishes in the SM for massless neutrinos. Extending the SM to include neutrino masses induces charged LFV via chirality flipping dipole amplitudes, which are however proportional to the fourth power in the ratio of neutrino mass splitting to $W$ mass, giving, e.g., for the LFV decay $\mu \rightarrow e\gamma$ a branching fraction of roughly $10^{-54}$ [5], depending on the neutrino mixing angle $\theta_{13}$. This is an unobservably tiny branching fraction so that the search for charged LFV probes new physics without SM contamination.

Experimentally, no evidence for charged LFV has been found so far. It is searched for in a variety of modes including the neutrinoless decays of a heavy lepton into a light one under emission of a radiative photon, or of a heavy lepton into three light ones. Using muonic atoms it is also possible to look for $\mu-e$ conversion in the electromagnetic field of the nucleus. Finally, $\tau$ leptons provide a profuse field of LFV searches with 48 different final states studied so far (see [6] for a recent summary). A chronological overview of LFV limits is drawn in Fig. [1]. It witnesses the many orders of magnitude improvement in the sensitivity obtained during half a century of LFV experiments. The tightest absolute limits on LFV effects are obtained in $\mu$ decays and $\mu-e$ conversion experiments. However, because different new physics phenomena induce different LFV effects, a quantitative comparison between the limits is model-dependent.

The absence of charged LFV had important consequences in the early days of particle physics when the...
Charged-Lepton Flavour Physics

Figure 2. Possible supersymmetric contributions to the transition dipole diagrams mediating the LFV processes $\mu \rightarrow e\gamma$ (left) and $\mu N \rightarrow eN$ conversion (right).

concept of fermion generations was developed. Non-discovery of $\mu \rightarrow e\gamma$ and $\tau \rightarrow \mu\gamma$ established that $\mu$ and $\tau$ were indeed new elementary leptons, as opposed to excited states of composite lighter leptons. In analogy to the GIM mechanism, the absence of $\mu \rightarrow e\gamma$ also required to introduce the muon neutrino, prior to the $\nu_{\mu}$ discovery in 1962 [7], to cancel FCNC amplitudes [8].

Radiative lepton decays $\ell_1 \rightarrow \ell_2\gamma$ proceed via dimension-five left and right-handed radiative transition amplitudes. The branching fraction can be written in the form [5]

$$B(\ell_1 \rightarrow \ell_2\gamma) = \frac{3\alpha}{32\pi} \left( |A_L|^2 + |A_R|^2 \right) \cdot B(\ell_1 \rightarrow \ell_2\nu\bar{\nu}) \cdot \alpha_{\text{QED}}. \quad (1)$$

For generic new physics at mass scale $\Lambda$ one can parametrise the left and right-handed dipole amplitudes by $A_L = A = 16\sqrt{2}\pi^2/G_F\Lambda^2$, where $G_F$ is the Fermi constant and $\Lambda$ the scale of the LFV interaction. The upper limit of $B(\mu \rightarrow e\gamma) < 1.2 \cdot 10^{-13}$, obtained by the MEGA experiment at the Los Alamos Meson Physics Facility in 2001 [9], thus translates into the stringent bound $\Lambda > 340$ TeV [5], which is well beyond the LHC reach for direct detection. Decays involving virtual photons, such as $\ell_1 \rightarrow \ell_2\ell_2\ell_2$ and $\mu \rightarrow e$ conversion, have an additional rate suppression factor $\alpha_{\text{QED}}$, but also probe different physics processes.

Figure 2 depicts example graphs for $R$-parity conserving supersymmetric contributions to the charged LFV processes $\mu \rightarrow e\gamma$ (left) and $\mu N \rightarrow eN$ conversion (right). The predicted rates depend on the value of the slepton mass mixing parameter involved (cf. [10, 11] and references therein). Lepton flavour violation is also naturally present in $R$-parity violating models, where the strength of the effects is governed by the size of trilinear lepton number violating couplings involving sleptons and leptons ($\lambda$), and squarks, leptons and quarks ($\lambda'$) in the supersymmetric superpotential [12].

2.1 A new limit on $B(\mu^+ \rightarrow e^+\gamma)$ by the MEG experiment

The MEG experiment [13-14] uses the presently most powerful quasi-continuous muon beam produced at the PSI (Switzerland) $\pi E5$ beam line. Positive 29 MeV surface muons hit with $3 \cdot 10^7$ Hz rate a thin stopping target that is surrounded by the MEG detector. The muon decay rate measured by MEG effectively has no time structure, because the $2.2\mu$s muon lifetime is long compared to the 50 MHz radio-frequency structure of the proton cyclotron producing the muons. MEG consists of a positron spectrometer (drift chamber) immersed in a gradient magnetic field that sweeps the produced positrons out of the interaction region, a time-of-flight counter, and a 900 litre liquid-xenon (LXe) scintillation detector outside of the magnet, measuring the photon incidence, time and energy. The solid-angle acceptance around the target is 10%.

The $\mu^+ \rightarrow e^+\gamma$ signal events are characterised by back-to-back, in-time monoenergetic (52.8 MeV) positron-photon pairs. Their measured energies, polar and zenith opening angles, and time difference are used to separate them from backgrounds, which are dominated by accidental coincidence of a positron from standard $\mu^+ \rightarrow e^+\nu\bar{\nu}$ decays and a photon from radiative $\mu^+ \rightarrow e^+\gamma\nu\bar{\nu}$ decays, bremsstrahlung or positron annihilation in flight. The reliance on a precise back-to-back signature invalidates the use of negative muons, which would form muonium atoms in the target that would smear out the two-body kinematics.
The dominance by accidental background (that increases quadratically with the muon intensity), motivates the use of a less intense continuous beam rather than an intense pulsed beam. Ultimately, this background imposes a limitation on further progress in this channel with the current experimental techniques.

In 2010, the MEG Collaboration has released a preliminary result from the analysis of the 2009 data sample [15], comprising $6 \cdot 10^{13} \mu^+$ decays in the target. More than – for the null hypothesis – expected events in the signal region were found, leading to a larger than expected 90% CL upper limit on $B(\mu^+ \rightarrow e^+\gamma)$ of $1.5 \cdot 10^{11}$, compared $6.1 \cdot 10^{12}$ expected. MEG has reanalysed the 2009 data in 2011, confirming that the excess of events is compatible with background-only at the 8% level, and also included the larger 2010 data set to a total $\mu^+$ yield of $1.8 \cdot 10^{14}$. The 2010 data benefited from an improved LXe waveform time resolution, but had slightly worse positron tracking resolution due to larger noise levels in the drift chamber [16]. The two-dimensional energy, angular and timing distributions of the selected events in the signal regions for the 2009 (left) and 2010 data sets (right) are shown in Fig. 3. The 2010 data did not reproduce the 2009 excess of signal-like events. MEG quotes the combined 90% CL upper limit [16] on $B(\mu^+ \rightarrow e^+\gamma)$

$$B(\mu^+ \rightarrow e^+\gamma) < 2.4 \cdot 10^{-12},$$

compared to an expected limit of $1.6 \cdot 10^{-12}$. This result is statistically limited. Systematic uncertainties are dominated by inaccuracies in the likelihood model and normalisation factors that should partly decrease with more statistics. The MEG experiment continues data taking in 2011 and 2012 to explore the $\mu^+ \rightarrow e^+\gamma$ decay down to the design sensitivity of several $10^{-13}$.

The authors of [17] have explored the potential of the MEG experiment (and others) in terms of supersymmetric GUT SO(10) MSUGRA models, which embed the seesaw mechanism and relate the neutrino Yukawa couplings to those of the up quarks making them naturally large [18] so that sizable LFV effects are introduced by the renormalisation group evolution. The ignorance of the Yukawa couplings between left and right-handed neutrinos is treated with the use of two extreme scenarios: minimal (CKM-like) and maximal (PMNS-like) mixing. Allowing MSUGRA parameter ranges of $m_0 < 5$ TeV, $-3m_0 < A_0 < 3m_0$, $\text{sign}(\mu) = \pm$, it is found that the new MEG limit excludes the maximal mixing case for large values of $\tan\beta$ and irrespective of the $m_{1/2}$ value (cf. Fig. 6 in [17]).

### 2.2 Muon to electron conversion

The capture of a muon in an atom and its neutrinoless conversion to an electron in the recoil field of the nucleus is called $\mu-e$ conversion (cf. right-hand graph in Fig. 2 for a supersymmetric diagram of a $\mu-e$ conversion process). In a $\mu-e$ conversion experiment slow negatively charged muons are guided via gradient magnetic fields to hit a stopping target where they are quickly captured by an atom (within $\sim 10^{-10}$ s) and
Charged-Lepton Flavour Physics

cascade down to 1S orbitals. There, the $\mu^-$ either decays (with rate of $\sim 5 \cdot 10^3 \text{ Hz}$), is weakly captured by the nucleus which undergoes $\beta$ decay (exceeding the muon decay rate for heavy atoms), or converts in an LFV process to an electron via virtual photon exchange with the nucleus. The $\mu^-e^-$ conversion gives rise to a single monoenergetic electron of 104.96 MeV for Al atoms and 95.56 MeV for Au, where the deviation from the muon mass is due to the muonic atom binding energy and the nucleus recoil energy. This simplicity and distinctive signature (very low background electron rate at 105 MeV, no accidents for single particle signature) allows extremely high rates and thus a very sensitive measurement.

The experimental observable is the conversion-to-capture ratio

$$R_{\mu e}(A, Z) = \frac{\Gamma(\mu^- + N(A, Z) \to e^- + N(A, Z))}{\Gamma(\mu^- + N(A, Z) \to \text{all } \mu^-\text{ captures})},$$

where $A$ and $Z$ are the atomic mass and charge number, respectively. The dependence of the ratio on the atom used can be exploited to distinguish new physics models after a discovery [19]. The denominator in Eq. 3 requires the knowledge of the total number of muon captures that can be measured from standard processes. Owing to the virtual interaction of the lepton and nucleus systems, $\mu^-e^-$ conversion is sensitive to classes of contact interaction models that do not contribute to $\mu \to e\gamma$ [11]. The conversion process might also exhibit enhanced sensitivity to supersymmetric Higgs exchange, which can be used to discriminate between models [19][20]. On the other hand, the sensitivity to generic chirality flipping dipole LFV amplitudes of new physics is reduced by factors $1/238, 1/342, 1/389$ in branching ratios for Ti, Pb and Al targets, respectively [5][21][22]. This requires a more precise measurement of $R_{\mu e}(A, Z)$ than that of $B(\mu \to e\gamma)$ for equal sensitivity, and hence $\mu^-$ rates of challenging $10^{11} \text{ Hz}$. Because no negative surface muon beams can be used, the beam will have a broader momentum spectrum and is contaminated by in-time particle backgrounds, mainly pions.

The best current limit on $\mu^-e^-$ conversion has been obtained by the SINDRUM-II experiment at PSI in 2006 using a gold target. They find $R_{\mu e}(Au) < 7 \cdot 10^{-13}$ at 90% CL [23] (cf. Fig. 1). The extrapolated MEG sensitivity for $\mu^+ \to e^+\gamma$ of $10^{-13}$ requires $R_{\mu e}(A, Z) < 10^{-10}$. Such an accuracy is in reach of the proposed experiments Mu2e (FNAL, USA) [24] and COMET (J-PARC, Japan) [25], which have both passed important approval steps. Their goal is to achieve a sensitivity down to 2–3 $\cdot 10^{-17}$ by the year 2018, which requires to produce a total of $5 \cdot 10^{19}$ muons. The experimental approaches of Mu2e and COMET are similar, albeit with some specific differences. Mu2e uses pulsed beams of 0.6 MHz to eliminate prompt backgrounds (e.g., radiative pion capture), a pulse extinction of $10^{-10}$ after 0.7 $\mu$s, and exploits the late muonic atom decays ($\tau \sim 1 \mu$s) for the conversion measurement. A magnetic bottle traps pions produced by proton bombardment in a target, which decay into accepted muons. Gradient magnetic fields guide the muons through an S-shaped beam line from the production to the stopping target to increase the muon acceptance and momentum selection, and to evacuate loopers. Collimators reduce backgrounds from particles other than muons. For detection, the atoms pass through a tracking detector and are stopped in a calorimeter. The decay electrons describe a helix trajectory in the gradient field of a solenoid where their momentum is precisely measured. The expected event yields for $R_{\mu e} = 10^{-16}$ are ~4 signal and 0.2 background events (dominated by radiative pion capture and decay-in-orbit muons). The multiple ring structure at FNAL allows to run Mu2e without interfering with the NOvA operation. COMET uses a C-shaped solenoid for improved muon momentum selection prior to hitting the stopping target, and also a C-shaped detector section (before the tracker) to eliminate low-energetic decay-in-orbit muons. Fascinating long-term upgrade projects, using muon storage rings that can improve the $\mu^-e^-$ conversion sensitivity by two orders of magnitude would be offered by an experiment at the Project-X proton accelerator complex at FNAL [26] and by the PRISM/PRIME project [27] at J-PARC (site not fixed).

2.3 Lepton flavour violation in $\tau$ decays

The lower available fluxes of $\tau$ production in $e^+e^-$ accelerators renders the search for LFV in $\tau$ decays more challenging than for muons, which are conveniently produced from pion decays (cf. [28] for a discussion.
Figure 4. Correlation between $\mu \rightarrow e\gamma$ and $\tau \rightarrow \mu\gamma$ branching fractions for various values of the third generation right-handed neutrino mass, $m_{N3}$, and the PMNS mixing angle, $\theta_{13}$, in a minimal supersymmetric seesaw model and assuming the MSUGRA point SPS1a [11]. The shaded areas indicate the experimentally excluded regions. Figure taken from [11] (modified).

What is the expected sensitivity to new physics of $\tau \rightarrow \ell\gamma$ compared to $\mu \rightarrow e\gamma$? This question can be addressed in specific new physics models by comparing the predicted branching fractions as a function of the model parameters. Such a study has been performed in [11] the results of which, for a minimal supersymmetric seesaw model and assuming the MSUGRA point SPS1a, is shown in Fig. 4. The various regions correspond to different assumptions for the heavy neutrino mass and the $\theta_{13}$ mixing angle. If the recent T2K result [24] on $\nu_\mu \rightarrow \nu_e$ appearance is confirmed (the significance of the current $\nu_e$ appearance excess is evaluated to be 2.5σ), $\theta_{13}$ should be larger than 5° hence effectively excluding the $m_{N3} = 10^{14}$ GeV case. A large mixing angle leads to similar contributions to both LFV decays which renders the $\tau$ channel non-competitive. Similar results are found in [35], where also a study using SU(5) without right-handed neutrinos is performed exhibiting larger differences between the $\tau \rightarrow \ell\gamma$ and $\mu \rightarrow e\gamma$ branching fractions, although the predicted effects are smaller in general than for supersymmetric GUT seesaw models.

3. Electric dipole moments

Elementary particles are predicted to be non-spherical, distorted by an electric dipole moment (EDM). However, as for charged LFV, EDMs are predicted to be undetectably tiny in the SM. Thus, any hint for a non-zero EDM would be a clean probe for physics beyond the SM, and indeed many SM extensions predict EDMs that are detectable by current experiments.
Electric dipole moment are CP-violating. The Hamiltonian of a system with magnetic moment, $\mu$, and EDM, $d$, immersed into magnetic and electric fields, $\vec{B}$ and $\vec{E}$, is given by $H = -\mu \vec{B} \cdot \hat{S} - d \vec{E} \cdot \hat{S}$ (describing a magnetic and electric Zeeman effect), where $\hat{S}$ is the unit spin vector. Applying $P$ and $T$ transformations on $H$ we find that the product $\vec{B} \cdot \hat{S}$ transforms even under both $P$ and $T$, while $\vec{E} \cdot \hat{S}$ transforms odd under these so that, assuming $CPT$ invariance, a non-zero EDM is CP non-conserving.

All experiments searching for EDMs follow the same basic principle. A particle with spin-1/2 immersed into magnetic and electric fields sees its spin vector precessing with Larmor frequency $\omega_{\uparrow\uparrow} = 2(\mu B + dE)/\hbar$, where the arrows indicate that both $B$ and $E$ fields have parallel orientation. Given the strong existing limits on $d$, a small value of $d \sim 10^{-26}$ e·cm in an electric field of 10 kV/cm induces a tiny precession frequency of only $0.1 \mu$Hz. This frequency corresponds to a magnetic field strength of 20 pico Gauss for a neutron [36]. Given that already the magnetic field of the earth amounts to 0.2–0.7 Gauss, it is obviously impractical to measure the $E$-induced offset and thus $d$ directly. The effect of $B$ (if time independent) can be cancelled by flipping the sign of the $E$ field and thus determining the frequency difference $\Delta \omega = \omega_{\uparrow\uparrow} - \omega_{\uparrow\downarrow} = 4dE/\hbar$. The sensitivity of the experiment thus depends on the control of the $B$ field variations between two $E$ flips, and on the $E$ field strength. As we will later see, the effective $E$ field seen by the dipole can be strongly amplified in paramagnetic atoms and molecules.

Figure 5 depicts the hierarchy of scales between CP-odd sources and generic classes of observable EDMs. For completeness one should also add solid state EDM effects to the atomic scale. Figure inspired by [37,38].

Figure 5. Hierarchy of scales between CP-odd sources and generic classes of observable EDMs. For completeness one should also add solid state EDM effects to the atomic scale. Figure inspired by [11,37,38].
ions and atoms, also CP-odd pion-nucleon interactions must be considered (denoted $g_{eN\pi}$ in Fig. 5). When EDMs are studied at the atomic scale, one distinguishes CP-odd effects induced in paramagnetic and diamagnetic atoms or molecules. Paramagnetic atoms (named for their unpaired electrons, e.g. thallium), and molecules (e.g. ytterbium-fluorine), are mainly sensitive to the electron EDM and CP-odd electron-nucleon couplings (denoted $C_{S,P,T}$ in Fig. 5). Diamagnetic atoms (e.g. mercury) receive the same CP-odd contributions as paramagnetic atoms but they are strongly suppressed due to smaller Schiff shielding violation, so that contributions from pion-nucleon scattering must also be considered.

### 3.1 Neutron and proton EDMs

A chronological overview of the neutron EDM measurements is shown in Fig. 6. The use of ultra-cold neutrons (UCN) provided a large sensitivity boost in this very active research field. Techniques such as in situ diamagnetic comagnetometers allowed to reduce systematic uncertainties due to magnetic field fluctuations. The currently best limit of $|d_n| < 2.9 \times 10^{-26}$ ecm at 90% CL has been obtained by the Sussex-RAL-ILL experiment operating at the ILL-Grenoble, France [40]. We can use it to illustrate the strong CP problem, $|\theta| \sim |d_n| \cdot 2 \times 10^{16} < 5 \times 10^{-10}$, and the supersymmetry problem, $|d_n| \sim 10^{-23}$ ecm \cdot (300 GeV/$M_{\text{SUSY}}$)$^2$ \cdot $\sin\phi_{\text{SUSY}}$, where $M_{\text{SUSY}}$ and $\phi_{\text{SUSY}}$ are a generic supersymmetry mass scale and CP-odd phase value, respectively (see, e.g., [37]). Both parameters are subject to large suppression of unknown origin.

Further improvement in the neutron EDM sensitivity requires to increase the UCN density, which can, for example, be achieved with the use of superfluid $^4$He used to moderate and store UCNs. Future experiments [38] aim at sensitivities of (in units of $10^{-26}$ ecm) 0.5 and 0.05 for the nEDM (by 2013) and n2EDM experiment at PSI (2016), respectively, 1 for PNPI at ILL (2012), 0.3 for CryoEDM at ILL (2016), 0.03 for nEDM at SNS-ORNL (2020), 1 for nEDM at RCNP (2014), 0.1 and 0.01 for nEDM at TRIUMF (2017 and >2020).

A fascinating perspective for measurements of the proton and/or light ion EDMs offer new proposals at BNL, USA [41] and Jülich, Germany [41], with an anticipated sensitivity of $10^{-29}$ ecm [42]. The proposed experiments exploit a similar magic-gamma trick as used for the measurement of the muon anomalous magnetic moment in a homogeneous magnetic field, but here applied to a radial electric field that keeps
the particles on orbit. A magic proton moment of 0.7 GeV leads to aligned proton spin and momentum vector precession ($\omega_a = 0$), thus allowing a precise EDM measurement via the monitoring of vertical spin precession versus time. Assuming that the sensitivity to new physics is the same for protons and neutrons, these certainly are must explore experiments.

3.2 Electron EDM

Over many years the electron EDM was dominated by the famous Berkeley measurement using thallium atoms that achieved in 2002 a 90% CL upper limit of $|d_e| < 1.6 \cdot 10^{-27} \text{cm}$ [43]. Again, this limit cuts into the bulk predictions of, e.g., supersymmetry, left-right symmetric and multi-Higgs models, while the SM prediction lies even several orders of magnitude below that for the neutron EDM [44]. I will describe here a recent measurement performed at the IC-London, UK, using YbF molecules [45].

Paramagnetic atoms and molecules respond to a screening theorem by Schiff [46] that implies a vanishing net EDM for a system built entirely from pointlike, nonrelativistic constituents that interact only electrostatically. Schiff’s theorem is broken by magnetic and relativistic interactions, and by finite size effects, i.e., a misalignment between the distribution of charge and EDM in the atom or molecule. Schiff violation is stronger for heavy atoms (growing as $Z^3$) and even stronger for polarisable molecules. It leads to an enhancement of the applied electric field, with factors of roughly $-585$ for the spherical thallium and 1.4 million for the dipolar YbF. The YbF factor is given for an external $E$ field of 10 kV/cm, not rising linearly with the strength of the field due to saturation effects (see [47] and references therein). Other advantages of YbF over Tl are smaller systematic uncertainties, in particular that due to motional magnetic fields. A shortcoming, however, is the much smaller production rate of YbF.

The ICL YbF electron EDM experiment looks for a spin interferometer phase shift of the $F = 0, 1$ YbF hyperfine levels when the electric field is reversed. The principle of the table-top apparatus is depicted in Fig. 7 (taken from [45]). Laser ablated YbF molecules populating both hyperfine levels are depleted from $F = 1$ states via optical pumping using the 552 nm optical transmission line of YbF. The remaining molecules in the $F = 0$ ground state enter a pair of electric field plates that are magnetically shielded. A tuned 170 MHz radio-frequency (RF) pulse transfers the molecules from the ground state into the $F = 1$ hyperfine level, where they form a coherent $|F = 1, m_F = \pm 1\rangle/\sqrt{2}$ state. While travelling some time $T$, the magnetic and, if non-zero EDM, electric fields induce a phase shift [45] $\phi = (\mu_B B - d_e E_{\text{eff}}) T / \hbar$. Another RF pulse projects the phase-shifted molecules back to $F = 0$ with state function $\left( e^{i\phi} |1, 1\rangle + e^{-i\phi} |1, -1\rangle\right)/\sqrt{2}$. A fluorescence pump detector counts the $F = 0$ population that has a rate proportional to $\cos^2 \phi$. One can scan the counting rate and thus $\phi$ by modulating the external magnetic field, and generate a tiny observable phase shift $\Delta \phi = 2 d_e E_{\text{eff}} T / \hbar$ by reversing

**Figure 7.** Sketch of the ICL YbF electron EDM experiment [45] (modified). Pulsed YbF molecules travel from the left to the right in-between the electric field plates.
the electric field. In practice, the $B$ and $E$ fields as well as several other parameters of the apparatus are switched in a random sequence between each beam pulse to track and minimise systematic correlations.

A total of 25 million YbF beam pulses, distributed throughout six thousand data blocks taken in 2010, give eight statistically independent measurements corresponding to manual reversal states of the apparatus. Combined they yield $d_e = (2.4 \pm 5.7_{\text{stat}} \pm 1.5_{\text{syst}}) \cdot 10^{-28}$ ecm, and a 90% CL upper limit of $|d_e| < 10.5 \cdot 10^{-28}$ ecm. The systematic error is currently dominated by the uncertainty in the uniformity of $E$ between sign flips [45]. This pioneering measurement has great potential in spite of the, yet, relatively little improvement over the 2002 thallium result. The present result is statistically limited, and systematic errors are expected to be reducible to a level smaller than $10^{-29}$ ecm. The ICL group aims at a factor of ten sensitivity improvement within a few years, with the final goal of reaching a factor of hundred improvement. Several other EDM experiments, based on electron spin precession in atoms, molecules, molecular ions or solids are under development.

4. Tau-lepton physics

Last year celebrated the 20th anniversary of the Tau Workshop series which started at LAL-Orsay in 1990. During that period there was magnificent progress in tau-lepton physics through the LEP, CLEO, $B$-factory, BES, VEPP-2M, and neutrino experiments. Early Tau Workshops concentrated on the consolidation of the tau as a standard lepton without invisible decays and with universal couplings. Increased data samples as well as better understanding and methods allowed the experiments to study electroweak and QCD physics with tau leptons leading to precision measurements of fundamental SM parameters such as $\sin^2 \theta_W$, $\alpha_s$, and $|V_{us}|$.

Whereas the four LEP experiments (1989–2000, CERN, Switzerland) collected each a data sample of roughly 165 thousand $Z \to \tau\tau$ events, CLEO (1979–2008, Cornell, USA) disposed already of about 3.6 million tau pairs, albeit with less efficient and pure selection than at LEP. The $B$-factory experiments BABAR at SLAC, USA and Belle at KEK-B, Japan accumulated breathtaking 500 million and 900 million tau pairs, respectively. Consequently, these experiments concentrate on the measurement of rare modes and searches for new physics: lepton flavour violation in tau decays, charged weak current universality tests, rare branching fractions, second class currents (isospin violation), and $CP$ violation. Phenomenological work on the determination of $\alpha_s$ and $|V_{us}|$ from tau branching fractions and spectral functions are also actively pursued.

4.1 Tau branching fractions and tests of universality

The most recent summary of the tau branching fractions is available from the Heavy Flavour Averaging Group (HFAG) [6] (see tau section). The dominant leptonic and hadronic tau branching fractions have been measured to great precision at LEP while running at the $Z$ resonance. The ALEPH experiment in addition performed a global analysis of all tau hadronic modes imposing unitarity [48]. The $B$-factory experiments also contributed with several new measurements, in particular improving the modes with kaons owing to their superior particle identification capabilities. The PDG group [49] noticed a puzzling tendency when comparing the total of 16 $B$-factory measurements (upper limits and exotic searches not included) with their counterparts from LEP: all but one $B$-factory results lie below those from LEP (cf. Fig. 8). A feature that requires further scrutiny.

The measurements of the branching fractions involving leptons allow one to test the three-generation universality of the charged weak current. The HFAG finds for the weak coupling ratio $|g_\mu/g_\tau|$, obtained from the ratio of the $\tau \to \mu \bar{\nu}_\mu$ to $\tau \to e\bar{\nu}_e$ world average branching fractions (corrected for mass-dependent effects), $1.0018 \pm 0.0014$ [6], which is a factor of seven more precise than the measurement of the corresponding on-shell $W$ leptonic branching fraction ratio [49]. It is of similar precision as the universality tests performed in neutral current reactions at LEP, giving 0.28% from a comparison of the $Z \to \ell\ell$ branching
fractions, and 0.13% from comparing the effective weak axial coupling $g_{A,e}/\mu$ \cite{50}. Universality of the ratios $|g_\tau/g_e|$ and $|g_\tau/g_\mu|$ can be tested by comparing the measured tau lepton branching fractions with the predicted ones using the tau and muon lifetimes and correcting for mass and radiative effects. The HFAG computes the world average ratios $1.0027 \pm 0.0021$ and $1.0008 \pm 0.0021$, respectively. Finally, the ratio $|g_\tau/g_\mu|$ can also be precisely determined with the ratio of the $\tau \to h\nu$ to $h \to \mu\nu$ ($h = \pi, K$) branching fractions, corrected for mass and radiative effects, which gives $0.9949 \pm 0.0029$. None of these tests reveals a significant deviation from universality.

### 4.2 Second class currents

In tau decays the charged weak current is classified according to its $G$-parity, where $J^{PG} = 0^{−−}, 1^{+−}$ currents ($\pi, a_1, \ldots$) produce an odd number of pions in the final state, and $J^{PG} = 1^{+−}$ currents ($\rho, \ldots$) produce an even number of pions. These are denoted first class currents. Second class currents \cite{51} (SCC) have opposite spin-parity $J^{PG} = 0^{−+}, 0^{−−}, 1^{++},$ or $1^{−−}$. They violate isospin symmetry and thus vanish in the strict isospin limit. Their branching fractions are expected to be proportional to the $u,d$ quark mass difference-squared. Examples for SCC are the decays $\tau \to \eta\pi\nu$ and $\tau \to \omega\pi\nu$, which may be dominantly mediated by the $a_0(980)$ and $b_1(1235)$ resonances, respectively. Estimates predict $B(\tau \to \eta\pi\nu) = (1.3 \pm 0.2) \cdot 10^{-5}$ (see \cite{52,53} and references therein). No SCC mode has been observed to date. The best current experimental limit of $9.9 \cdot 10^{-5}$ at 90% CL has been obtained by BABAR using the full available statistics \cite{54}. Since this search is not free of background a much larger data sample is required to be able to discover this mode if the branching fraction is as expected.

### 4.3 CP violation in tau decays

CP violation in tau decays with strangeness occurs in the SM via mixing-induced CP violation in the neutral kaon system. The asymmetry

$$A_Q = \frac{\Gamma(\tau^+ \to \pi^+ K_0^{0}\nu_\tau) - \Gamma(\tau^- \to \pi^- K_0^{0}\bar{\nu}_\tau)}{\Gamma(\tau^+ \to \pi^+ K_0^{0}\nu_\tau) + \Gamma(\tau^- \to \pi^- K_0^{0}\bar{\nu}_\tau)}$$

(4)
Andreas Hoecker

is predicted to be $A_{SM}^{SM} \sim 2\Re(e_K) = (0.33 \pm 0.01)\%$ \cite{55}. Reference \cite{56}, which appeared after the conference, points out that this prediction \cite{55} for the $K^0_\pi$-only terms contains a sign mistake and that only when taking into account $K^0_\pi-K^0_\eta$ interference the positive sign is approximately recovered. Deviations from $A_{SM}^{SM}$ should have new physics origin as is possible, e.g., in multi-Higgs models \cite{57}. Results consistent with the SM were previously found in $D^\pm \to K^0_\pi\pi^\pm$ \cite{58} and in an angular analysis of $\tau^\pm \to \pi^\pm K^0_\eta\nu$ \cite{59}.

For the conference, BABAR released a new result for $A_Q$ \cite{60} based on the full available data set ($476 \text{ fb}^{-1}$). The analysis uses electron and muon tagged events (recoil side). The raw asymmetry is corrected for different nuclear interaction cross sections and for feed-through from $K^0_\pi K^\pm (\geq \pi^0)$ and $K^0 K^0_\pi^\pm$ decays, where $A_{SM}^{SM}$ is assumed for the latter correction. BABAR finds $A_Q = (-0.45 \pm 0.24 \pm 0.11)\%$, which deviates by approximately 3σ from $A_{SM}^{SM}$. However, as argued in \cite{56}, the precise prediction of $A_Q$ as measured by BABAR must account for the decay time interval over which it is measured, which depends on the experimental conditions and analysis requirements applied.

4.4 Tau hadronic spectral functions and QCD

QCD studies using the tau hadronic width and spectral moments computed from the tau hadronic spectral functions have traditionally been the most active field of phenomenological studies involving tau physics (see, e.g., \cite{61} for a review). In particular the measurements of the complete vector and axial-vector tau hadronic spectral functions by ALEPH \cite{48, 62, 63} and OPAL \cite{64} triggered widespread interest. Most prominently, tau decays allow an accurate determination of $\alpha_s$, from the comparison of the non-strange tau hadronic width, $R_{\tau, V+A} = 3.4771 \pm 0.0084$ \cite{65}, precisely obtained using unitarity and universality from the measurements of the tau leptonic branching fraction and the tau lifetime, and subtracting the strangeness contribution, with the SM prediction from essentially perturbative QCD. Small nonperturbative contributions are fitted from data using the spectral moments. Quark-hadron duality violations are usually assumed to be negligible due to the suppression of the spectral moments at the tau mass scale (see the critical discussion in \cite{65, 66}). The perturbative QCD prediction of $R_{\tau, V+A}$ benefits, as the electroweak fit to the $Z$ hadronic width, from an NNNLO calculation of the massless perturbative Adler function \cite{67}. Unfortunately, an ambiguity in the perturbative treatment does currently not allow to fully exploit the available precision \cite{68, 71} in tau decays.

From the combined fit of $\alpha_s$ and the nonperturbative terms to $R_{\tau, V+A}$ and several spectral moments, and after the renormalisation group evolution from the tau to the $Z$ mass, one finds

$$\alpha_s(M_Z) = 0.1200 \pm 0.0005_{\text{exp}} \pm 0.0008_{\text{theo}} \pm 0.0013_{\text{CIPT/FOPT}} \pm 0.0005_{\text{evol}},$$

(5)

where the first error is experimental, the second theoretical, the third accounts for half of the difference between the two perturbative treatments (denoted as contour-improved and fixed-order perturbation theory, of which the average result is used as central value for $\alpha_s(M_Z)$), and the last error accounts for the evolution uncertainty (four-loop evolution \cite{72} with three-loop quark-flavour matching \cite{73, 74}). The nonperturbative contributions in \cite{5} are taken from \cite{68}. Equation (5) is in excellent agreement with the NNNLO result from the electroweak fit to (mainly) the $Z$ hadronic width $\alpha_s(M_Z) = 0.1193 \pm 0.0028$ \cite{75}, providing a precise test of the asymptotic freedom property of QCD. The evolution path of $\alpha_s(m_\tau)$ to higher scales is shown in the upper plot of Fig. \cite{5} The evolution is compared in this plot with other $\alpha_s$ determinations compiled in \cite{76}.

4.5 Determination of $|V_{us}|$

The amount of net strangeness production in tau decays is directly proportional to the CKM element $|V_{us}|^2$. Accurate extractions of this element have been performed with the use of three different methods: (i) comparing the measured branching fraction of the decay $\tau^- \to K^-\nu$ with its SM prediction, which depends on the kaon decay constant taken from Lattice QCD and on radiative corrections, (ii) comparing the measured
Figure 9. Top plot: evolution of $\alpha_s(m_\tau)$ given in Eq. (5) to higher scales $\mu$ using the four-loop RGE and the three-loop matching conditions applied at twice the heavy quark-pair thresholds (hence the discontinuities). The evolution is compared with independent measurements (taken from the compilation [77]), covering $\mu$ scales that vary over more than two orders magnitude. Bottom: the corresponding $\alpha_s$ values evolved to $M_Z$. The shaded band displays the tau decay result within errors. Figure courtesy of Z. Zhang.

ratio of the $\tau^- \to K^- \nu$ and $\tau^- \to \pi^- \nu$ branching fractions to the SM prediction, and (iii) comparing the inclusive tau strange hadronic width with its SM prediction. The latter two methods also depend on $|V_{ud}|^2$.

The results for $|V_{us}|$ obtained from these methods are shown in the left panel of Fig. [10] and are compared to other evaluations and to the CKM fit result assuming unitarity [6]. The agreement between the tau inclusive result and the CKM fit is marginal. The inclusive method [78] uses the observable $|V_{us}|^2 = R_{\tau,S=1}/(R_{\tau,S=0}/|V_{ud}|^2 - \delta R_{\tau}^{SM}(\alpha_s, m_s))$ [79], where the SM prediction of the mass-dependent term, $\delta R_{\tau}^{SM}(\alpha_s, m_s)$, exhibits slow convergence in the perturbative series [80, 81], which leads to a hard-to-quantify theoretical uncertainty. The inclusive method may also suffer from potentially unmeasured modes, which are not included in the systematic uncertainties. Finally, the trend to smaller branching fractions from the $B$-factory experiments has a non-negligible impact on this quantity. Without the $B$-factory data, $|V_{us}|$ from the inclusive determination would increase to approximately 0.2213. A precise measurement of the full strange spectral function by the $B$-factory experiments should help to test the inclusive method.

The right panel of Fig. [10] shows the experimental results on $|V_{us}|$ versus $|V_{ud}|$ compared to the CKM fit constraint [82]. Good agreement with unitarity of the first row is observed.
5. Anomalous magnetic moment of the muon

The Dirac equation predicts for elementary leptons, \( \ell \), a magnetic moment, \( \vec{M} = (g_\ell e/2m_\ell) \cdot \vec{S} \), with gyromagnetic ratio \( g_\ell = 2 \) \[83\]. Quantum fluctuations lead to a small calculable deviation from \( g_\ell = 2 \), parametrised by the anomalous magnetic moment \( a_\ell \equiv (g_\ell - 2)/2 \). That quantity can be accurately measured and, within the SM, precisely predicted. Hence, comparison of experiment and theory tests the SM at its quantum loop level. A deviation in \( a_\exp \) from the SM expectation would signal effects of new physics, with current sensitivity reaching up to mass scales of \( \mathcal{O}(\text{TeV}) \) for \( \ell = \mu \) \[84, 85\]. Considering the expected quadratic dependence of new physics contributions on the lepton mass \[84\], and the current experimental uncertainties on \( a_\exp \), the muon \( g - 2 \) is roughly 50 times more sensitive to new physics than the electron one\(^1\), while the tau \( g - 2 \) has not yet been measured to significant precision. For recent and very thorough muon \( g - 2 \) reviews, see Refs. \[91, 92\].

### 5.1 Experimental result

The E821 experiment at Brookhaven National Lab (BNL), USA, studied the precession of \( \mu^+ \) and \( \mu^- \) in a uniform external magnetic field perpendicular to the muon spin and orbit plane as they circulated in a cyclotron. At a *magic* muon momentum of 3.09 GeV (or magic \( \gamma = 29.3 \)), and negligible \( \mu \) EDM, the observed difference between spin precession frequency and cyclotron frequency, \( \omega_a \), is independent of the focusing electric field and is given by \( \omega_a = a_\mu Bc/m_\mu c \). Following a doubly blinded analysis strategy, E821 found the charge averaged result \[93, 95\]:

\[
a_\mu^{\exp} = (11,659,087.3 \pm 2.8) \times 10^{-10},
\]

\(^1\) In spite of the breathtaking accuracy of the most recent electron \( g - 2 \) measurement by the Harvard group \[86\], giving \( a_\exp^{\text{e}} = (11,596,521.807.3 \pm 2.8) \times 10^{-10} \), exploiting this measurement to search for new physics is limited by the knowledge of the electromagnetic fine structure constant, \( \alpha \). Inserting independent measurements of \( \alpha \) from atom recoil analyses \[87, 90\], effectively reduces the above accuracy by a factor of 20.
Charged-Lepton Flavour Physics

\[ a_\mu^{SM} = a_\mu^{QED} + a_\mu^{EW} + a_\mu^{had}. \]  \hspace{1cm} (7)

The QED part includes all photonic and leptonic \((e, \mu, \tau)\) loops starting with the classic \(\alpha/2\pi\) Schwinger contribution [97]. It has been computed through 4 loops and estimated at the 5-loop level [98–104]. Employing \(\alpha^{-1} = 137.035999084 \pm 51\), determined [86,98–105] from the electron \(a_e\) measurement, leads to \(a_\mu^{QED} = (116.584718.09 \pm 0.15) \cdot 10^{-11}\), where the error results from uncertainties in the coefficients of the perturbative series and in \(\alpha\). Loop contributions involving heavy \(W^\pm, Z\) or Higgs particles are collectively labelled as \(a_\mu^{EW}\). They are suppressed by at least a factor of \((\alpha/\pi) \cdot (m_\mu/m_W)^2 \simeq 4 \cdot 10^{-9}\). At 1-loop order one finds \(a_\mu^{EW}[1\text{-loop}] = 194.8 \cdot 10^{-11}\) [106]. Two-loop corrections are found to be relatively large and negative \(a_\mu^{EW}[2\text{-loop}] = (-40.7 \pm 1.0 \pm 1.8) \cdot 10^{-11}\) [107–113], where the errors stem from quark triangle loops and the assumed Higgs mass range between 100 and 500 GeV. The 3-loop leading logarithms are negligible [107,114], \(\mathcal{O}(10^{-12})\), implying for the total weak contribution \(a_\mu^{EW} = (154 \pm 1 \pm 2) \cdot 10^{-11}\).

5.3 Hadronic contribution

Hadronic loop contributions to \(a_\mu^{SM}\) give rise to its main theoretical uncertainties. At present, those effects are not calculable from first principles, but such an approach, at least partially, may become possible as lattice QCD matures (cf. [115] for a lattice calculation using two-flavour QCD which results, however, in an underestimate of \(a_\mu^{SM,n_f=2}\)). Instead, one currently relies on a dispersion relation approach to evaluate the lowest-order hadronic vacuum polarisation contribution, \(a_\mu^{had,LO}\), from corresponding cross section.

Figure 11. Feynman graphs contributing to \(a_\mu^{SM}\) and possible new physics processes.

where the first error is statistical and the second systematic. This result represents about a factor of 14 improvement over the classic CERN experiments of the 1970’s [96].

5.2 Standard Model prediction

The SM prediction for \(a_\mu^{SM}\) is conveniently divided into three parts (see Fig. 11 for representative Feynman diagrams)

\[ a_\mu^{SM} = a_\mu^{QED} + a_\mu^{EW} + a_\mu^{had}. \]  \hspace{1cm} (7)

The QED part includes all photonic and leptonic \((e, \mu, \tau)\) loops starting with the classic \(\alpha/2\pi\) Schwinger contribution [97]. It has been computed through 4 loops and estimated at the 5-loop level [98–104]. Employing \(\alpha^{-1} = 137.035999084 \pm 51\), determined [86,98–105] from the electron \(a_e\) measurement, leads to \(a_\mu^{QED} = (116.584718.09 \pm 0.15) \cdot 10^{-11}\), where the error results from uncertainties in the coefficients of the perturbative series and in \(\alpha\). Loop contributions involving heavy \(W^\pm, Z\) or Higgs particles are collectively labelled as \(a_\mu^{EW}\). They are suppressed by at least a factor of \((\alpha/\pi) \cdot (m_\mu/m_W)^2 \simeq 4 \cdot 10^{-9}\). At 1-loop order one finds \(a_\mu^{EW}[1\text{-loop}] = 194.8 \cdot 10^{-11}\) [106]. Two-loop corrections are found to be relatively large and negative \(a_\mu^{EW}[2\text{-loop}] = (-40.7 \pm 1.0 \pm 1.8) \cdot 10^{-11}\) [107–113], where the errors stem from quark triangle loops and the assumed Higgs mass range between 100 and 500 GeV. The 3-loop leading logarithms are negligible [107,114], \(\mathcal{O}(10^{-12})\), implying for the total weak contribution \(a_\mu^{EW} = (154 \pm 1 \pm 2) \cdot 10^{-11}\).
measurements and predictions \cite{116, 117}

\[
\alpha_{\mu, \text{LO}}^{\text{had}} = \frac{1}{3} \left( \frac{\alpha}{\pi} \right)^2 \int \frac{K(s)}{s} R_s^{(0)}(s),
\]

where \( R_s^{(0)}(s) \) denotes the ratio of the bare cross section for \( e^+e^- \) annihilation into hadrons to the pointlike muon-pair cross section at centre-of-mass energy \( \sqrt{s} \). The function \( K(s) \sim 1/s \) gives a strong weight to the low-energy part of the integral \cite{118}, such that \( \alpha_{\mu, \text{LO}}^{\text{had}} \) is dominated by the \( \rho'(770) \rightarrow \pi^+\pi^- \) resonance.

There has been a huge, twenty-years long effort by experimentalists and theorists to reduce the error on \( \alpha_{\mu, \text{LO}}^{\text{had}} \). It featured improved \( e^+e^- \) cross section data from the Novosibirsk, Russia accelerator facilities, more use of perturbative QCD to replace inaccurate data points, the development of the radiative return technique which allows to exploit cross-section data from the high-luminosity \( \Phi \) and \( B \) factories, and the use of precise \( \tau \) hadronic spectral functions by applying isospin symmetry. The computation of the integral (8) proceeds in different steps. Exclusive cross-section measurements are summed up to obtain \( R_s^{(0)}(s) \) for \( \sqrt{s} \leq 1.8 \text{ GeV} \). Unmeasured modes are estimated from measured ones using isospin relations. Perturbative QCD can be used to predict \( R_s^{(0)}(s) \) away from the quark thresholds in the quark-antiquark continuum. Comparisons of the QCD predictions with inclusive data, where available, exhibit good agreement with theory. Helpful here is the so-called global quark-hadron duality approximation, which uses the fact that essentially perturbative QCD can be used to predict integrals over hadronic spectral functions if a large enough spectrum is integrated over and if the endpoint of the integral is not too far from the continuum region. The same concept is used to extract \( \alpha_e \) from \( \tau \) decays. Experimental data are used for the evaluation of (8) in the charm anti-charm resonance region beyond the opening of the \( D\bar{D} \) threshold.

A significant improvement in the knowledge of the low-energy \( e^+e^- \) cross sections was obtained by realising \cite{120, 121} that the high luminosity available at the modern \( \Phi \) and \( B \) factories made it possible to exploit events with hard initial state photon radiation to measure the cross section of the process \( e^+e^- \rightarrow \text{hadrons}(s') \) at any energy \( \sqrt{s'} \) below \( \sqrt{s} \), the centre-of-mass energy of the experiment. It required the measurement of the corresponding radiative process, where the photon is emitted by the colliding electrons so that \( s' = s(1 - 2E_\gamma^2/\sqrt{s}) \), where \( E_\gamma \) is the centre-of-mass energy of the radiated photon. Figure 12 (bottom) shows the \( e^+e^- \rightarrow \pi^+\pi^- (\gamma) \) cross section measured by BABAR using this technique \cite{119}. The measurement is systematics dominated, with errors ranging between 0.5 and 1.4%. The top panel shows the ratio of the \( e^+e^- \rightarrow \mu^+\mu^- (\gamma) \) cross section between data and the prediction from QED. Good agreement is observed, which demonstrates that all relevant efficiencies and acceptance requirements (trigger, photon, tracking, particle identification, kinematic fit, acceptance) are understood. The comparison of different cross section data \cite{122} revealed a discrepancy between the most precise measurements by BABAR and KLOE \cite{123, 124}. In summer 2011, KLOE presented a new preliminary measurement \cite{125} of the two-pion cross section employing, as was done by BABAR, the \( \pi\pi(\gamma)/\mu\mu(\gamma) \) ratio for which radiation, luminosity and vacuum polarisation corrections, as well as several acceptance-related systematic uncertainties cancel. The ratio crucially relies on a well understood \( \pi/\mu \) separation in the detector. The analysis used 239 pb\(^{-1}\) of data, giving 3.4 (0.9) million \( \pi\pi(\gamma) (\mu\mu(\gamma)) \) events, and achieved an overall systematic precision of \( 1\% \). Good agreement with the previous KLOE results is found so that the observed discrepancy with BABAR is corroborated.

Precise BABAR data available for several higher multiplicity modes with and without kaons help to discriminate between older, less precise and sometimes contradicting measurements. Figure 13 shows as an example the cross section measurements and their averages for the channels \( e^+e^- \rightarrow \pi^+\pi^- 2\pi^0 \) and \( e^+e^- \rightarrow K^+K^-\pi^+\pi^- \). In several occurrences the older measurements overestimate the cross sections in comparison with BABAR, which contributes to the reduction in the newer evaluations of the hadronic loop effects. The BABAR data also greatly help to improve the estimates of unmeasured modes via isospin constraints from measured ones \cite{122}.

Summing the contributions from all the available \( \sigma(e^+e^- \rightarrow \text{hadrons}) \) modes and those evaluated with
perturbative QCD, the integral (8) gives 122
\[ a_{\mu}^{\text{had,LO}} = (6.923 \pm 4.2 \pm 3) \cdot 10^{-11}, \]
where the first error is experimental (dominated by systematic uncertainties), and the second due to perturbative QCD. New multi-hadron data from the BABAR experiment have increased the constraints on unmeasured exclusive final states and led to a small reduction in the hadronic contribution compared to previous evaluations.

Alternatively, one can use precise vector spectral functions from \( \tau \rightarrow \nu_{\tau} + \text{hadrons decays} \) that are related to isovector \( e^+e^- \rightarrow \text{hadrons cross sections by isospin symmetry. The } \tau \text{ data are subject to very different systematic uncertainties compared to the } e^+e^- \text{ data, thus providing a valuable cross check. Replacing } e^+e^- \text{ data in the two-pion and four-pion channels by the corresponding isospin-transformed } \tau \text{ data, and applying isospin-violating corrections (QED radiative corrections, charged versus neutral meson mass splitting and electromagnetic decays, giving } \Delta a_{\mu}^{\text{had,LO}} = (3.2 \pm 0.4\%) \text{ one finds} 122
\[ a_{\mu}^{\text{had,LO}} = (7.015 \pm 42 \pm 19 \pm 3) \cdot 10^{-11} (\tau), \]
where the first error is experimental, the second estimates the uncertainty in the isospin-breaking corrections applied to the \( \tau \) data, and the third error is due to perturbative QCD. The current discrepancy between the \( e^+e^- \text{ and } \tau \)-based determinations of \( a_{\mu}^{\text{had,LO}} \) has been reduced to 1.8σ with respect to earlier evaluations. New \( e^+e^- \text{ and } \tau \text{ data from the } B \text{-factory experiments BABAR and Belle have increased the experimental information. Reevaluated isospin-breaking corrections have also contributed to this improvement} 129. BABAR reported good agreement with the } \tau \text{ data in the most important two-pion channel} 119. The

remaining discrepancy with the older $e^+e^-$ and $\tau$ datasets may be indicative of problems with one or both data sets. It may also suggest the need for additional isospin-violating corrections to the $\tau$ data.

Higher order, $O(\alpha^3)$, hadronic contributions are obtained from dispersion relations using the same $e^+e^- \to$ hadrons data [128][130][131], giving $a_{\mu,\text{had, NLO}[\text{Disp}]} = (-98.4\pm0.6) \times 10^{-11}$, along with model-dependent estimates of the hadronic light-by-light scattering contribution [132], $a_{\mu,\text{had, NLO}[\text{LBL}]}$, motivated by large-$N_C$ QCD [133–136]. Following [134], one finds for the sum of the two terms $a_{\mu,\text{had, NLO}} = (7\pm26) \times 10^{-11}$, where the error is dominated by the light-by-light contribution.

Adding all SM contributions gives the $e^+e^-$ data based SM prediction

$$a_{\mu,\text{SM}} = (116591802 \pm 2 \pm 42 \pm 26) \times 10^{-11},$$

where the errors are due to the electroweak, lowest-order hadronic, and higher-order hadronic contributions, respectively. The difference between experiment and theory, $\Delta a_{\mu} = a_{\mu,\text{exp}} - a_{\mu,\text{SM}} = (287 \pm 63 \pm 49) \times 10^{-11}$ (with all errors combined in quadrature), represents an interesting but not yet conclusive discrepancy of approximately 3.6$\sigma$. All the recent estimates for the hadronic contribution compiled in Fig. 14 exhibit similar discrepancies. Switching to $\tau$ data reduces the discrepancy to 2.4$\sigma$, assuming the isospin-violating corrections are under control within the estimated uncertainties.

An alternate interpretation is that $\Delta a_{\mu}$ may be a new physics signal with supersymmetric particle loops. Such a scenario is quite natural, since generically, supersymmetric models predict [84] an additional contribution to $a_{\mu}$ of order

$$a_{\mu,\text{SUSY}} \simeq \pm 130 \times 10^{-11} \cdot \left(\frac{100 \text{ GeV}}{m_{\text{SUSY}}}\right)^2 \tan \beta,$$

where $m_{\text{SUSY}}$ is a representative supersymmetric mass scale, and $\tan \beta \simeq 3\text{–}40$ is a potential enhancement factor. Supersymmetric particles in the mass range 100–500 GeV could be the source of the deviation $\Delta a_{\mu}$. If so, those particles could be directly observed at the LHC. The experiments ATLAS and CMS at the LHC are searching for supersymmetry in a large variety of signatures already pushing the limits for squarks and gluinos beyond the TeV scale for the most sensitive searches in events with jets and missing transverse energy [138][139]. These limits, however, do not directly affect the loops contributing to $a_{\mu,\text{SUSY}}$, which are dominated by virtual gaugino and slepton exchange (cf. Fig. 11), or only in very constrained models [140].

New physics effects [84] other than supersymmetry could also explain a non-vanishing $\Delta a_{\mu}$. A recent popular scenario involves the “dark photon”, a relatively light hypothetical vector boson from the dark

---

**Figure 13.** Cross section data for the $e^+e^-$ final states $\pi^+\pi^-2\pi^0$ (left) and $K^+K^-\pi^+\pi^-$ (right). The BABAR data [126][127] improve the precision and resolve inconsistencies among earlier data sets. Figure taken from [122].
Figure 14. Compilation of recently published results for $a_\mu$ (in units of $10^{-11}$), subtracted by the central value of the experimental average [6]. The shaded band indicates the experimental error. The SM predictions are taken from: JN [92], DHMZ [122], and HMNT [130]. Note that the quoted errors do not include the uncertainty on the subtracted experimental value. Figure from [137].

matter sector that couples to our world of particle physics through mixing with the ordinary photon [141, 142]. As a result, it couples to ordinary charged particles with strength $\epsilon \cdot e$ and gives rise to an additional muon anomalous magnetic moment contribution $a_{\mu}^{\text{dark photon}} = (\alpha/2\pi) \cdot \epsilon^2 F(m_V/m_\mu)$, where $F(x)$ is a monotonously falling function with $F(0.1) = 0.8, F(1) = 0.2$. For values of $\epsilon \sim 1 - 2 \cdot 10^{-3}$ and $m_V \sim 10 - 100$ MeV, the dark photon, which was originally motivated by cosmology, can provide a viable solution to the muon $g - 2$ discrepancy. Searches for the dark photon in that mass range are currently underway at Jefferson Lab, USA, and MAMI in Mainz, Germany.

Despite the significant experimental and theoretical progress reported here, the situation of the muon $g - 2$ stays inconclusive. Proposals for new experiments based on different experimental approaches exist at FNAL [143] and J-PARC [144]. The FNAL proposal continues the established magic-$\gamma$ technique, but with higher proton rate than at BNL and less protons per bunch, a 900 m pion decay line (BNL: 80 m) leading to a smaller pion flash at the muon ring injection, zero-degree muons giving a 5–10 times larger muon yield per proton, and 5–10 times as many muons stored per hour than at the BNL experiment. In addition, improved detectors against signal pileup, new electronics, and a better shimming to reduce $B$-field variations should lead to a 2.5 (3) times smaller systematic error on the $B$-field ($\omega_a$). The experiment targets a 20 times better statistical error, and a final systematic error of $1.6 \cdot 10^{-10}$. The J-PARC proposal anticipates similar precision without a focusing electric field and hence no need to choose a particular magic $\gamma$. Ultra-slow muons ($p_\mu \sim 2.3$ keV), generated from laser-ionised muonium atoms, are used which have a transverse momentum dispersion that is significantly smaller than the longitudinal momentum, allowing the beam to circulate in the storage ring without focusing field.
6. Conclusions

All of us are passionately following the LHC experiments in their direct searches for electroweak symmetry breaking remnants and new physics at the TeV-scale energy frontier. Probing new physics orders of magnitude beyond that scale, and helping to decipher possible TeV-scale new physics discovered at the LHC requires to work hard on the intensity and precision frontiers.

Charged leptons offer an important spectrum of possibilities. Charged-lepton flavour violation and electric dipole moment measurements have Standard Model free signals, and current experiments and mature proposals promise orders of magnitude sensitivity improvement over the state of the art. The muon anomalous magnetic moment may already witness a deviation from the Standard Model. New physics models often strongly correlate all these sectors of particle physics.

Acknowledgements — I am grateful to Alessandro Baldini, Swagato Banerjee, Robert Bernstein, Michel Davier, Tim Gershon, Herve Hiu Fai Choi, Yoshitaka Kuno, Alberto Lusiani, Bogdan Malaescu, James Miller, Toshinori Mori, Steven Robertson, Karim Trabelsi, Graziano Venanzoni and Zhiqing Zhang for their help with the preparation of the talk. It is a pleasure to thank the organisers and the international advisory board of LP11 for giving me the opportunity to talk at this important conference and to visit the extraordinarily interesting and dynamic city of Mumbai.
